2. A treatise on the Elements of Algebra, for the use of Young Students; to which is added a Specimen of a Commentary on Newton's Universal Arithmetic; as also, A New Rule for determining the Form of an Assumed Infinite Series.—3. An Essay on Perspective: This was written at 19 years of age.—4. A New Theory of the Collision of Bodies.—5. A Course of Logic and Metaphysics.—With several smaller pieces.

His whole mathematical and philosophical works, except the first-mentioned article, were collected and published at Amsterdam, in 2 vols. 4to, to which is prefixed a critical account of his life and writings, by Professor Allamand.

G R A V I M E T E R, the name given by M. Guyton, to an instrument for measuring the specific gravities of bodies: he adopts this name rather than either areometer or hydrometer, because these latter terms are grounded on the supposition that the liquid is always the thing weighed; whereas, with regard to solids, the liquid is the known term of comparison, to which the unknown weight is referred.

Guyton's gravimeter is executed in glass, and is of a cylindric form, being that which requires the smallest quantity of fluid, and is on that account preferable, except so far as it is necessary to deviate for the security of a vertical position. It carries two basins, one of them superior, at the extremity of a thin stem, towards the middle of which, the fixed point of immersion is marked. The other, or lower basin, terminates in a point; it contains the ballast, and is attached to the cylinder by two branches. The moveable suspension, by means of a hook, has the inconvenience of shortening the lever which is to secure the vertical position.

The cylinder of this instrument is 0·71 inches diameter; and 6·85 inches in length. It carries in the upper basin an additional constant weight of 5·115 grains. These dimensions might be increased so as to render it capable of receiving a much more considerable weight; but this is unnecessary. M. Guyton has added a piece which he calls the plongeur, because in fact it is placed in the lower basin when used, and is consequently entirely immersed in the fluid. It is a bulb of glass loaded with a sufficient quantity of mercury, in order that its total weight may be equal to the constant additional weight, added to the weight of the volume of water displaced by this piece. It will be readily understood that the weight being determined at the same temperature at which the instrument was originally adjusted, it will sink to the same mark on the stem, whether it be loaded with a constant additional weight in the upper basin, or whether the effect of this weight be produced by the additional piece in the lower dish.

This instrument may be used for solids, as well as fluids, provided the absolute weight of the solid to be examined be rather less than the constant additional weight in the upper basin, which is 115 grains.

For liquids of less specific gravity than water, the gravimeter, without the additional weight above mentioned, weighs about 459 grains, in the dimensions before laid down. It would be easy to limit its weight to the greatest accuracy. We have therefore the range of one-fifth of buoyancy, and consequently the means of ascertaining all the intermediate densities, from water to the most highly rectified spirit, which is known to bear in this respect the ratio of 8 to 10, with regard to water.

When liquids of greater specific gravity than water are to be tried, the constant weight being applied below, by means of the additional piece, which weighs about 138 grains, the instrument can receive in the upper basin more than 4 times the usual additional weight, without losing the equilibrium of its vertical position. In this state it is capable of showing the specific gravity of the most concentrated acid. It possesses also another property, which is this; namely, that it may be employed as a balance to determine the absolute weight of such bodies as do not exceed its additional load. And the purity of water being known, it will indicate the degrees of rarefaction and condensation, in proportion to its own bulk.

To find the specific gravity of any solid by the gravimeter. Rule: "From the weight in the upper basin, when the instrument is properly immersed in the unknown fluid, take the weight which is placed with the body in the same scale at the like adjustment; the remainder is the absolute weight of the solid. Multiply this by the specific gravity of the fluid, and reserve the product. From the additional weight when the body is placed in the lower basin, take the weight when it was placed in the upper; the remainder will be the loss of weight by immersion. Divide the reserved by the loss by immersion, and the quotient will be the specific gravity of the solid with regard to distilled water, at the standard temperature and pressure."

To find the specific gravity of a fluid, proceed thus: "To the weight of the gravimeter add the weight required in the upper basin, to sink it in the unknown fluid. Again, To the weight of the gravimeter add the weight required in the same manner to sink it in distilled water. Divide the first sum by the second, and the quotient will be the specific gravity of the fluid in question."

GRAVITATION, the exercise of gravity, or the pressure a body exerts on another body beneath it by its weight. This is sometimes distinguished from gravity. Thus, M. Maupertuis, in his *Figure de la Terre*, takes gravity for that force by which a body would fall to the earth supposed at rest; and gravitation for the same, but diminished by the centrifugal force. It is only gravitation, or gravity thus blended with the centrifugal force, that we can usually measure by our experiments. Methods however have been found to distinguish what remains of the primitive gravity, and what has been destroyed by the centrifugal force.

It is one of the laws of nature, discovered by Newton, and now received by all philosophers, that every particle of matter in nature gravitates towards every other particle; which law is the main principle in the Newtonian philosophy. But what is called gravitation with respect to the gravitating body, is usually called attraction with respect to the body gravitated to. The planets, both primary and secondary, as also the comets, do all gravitate towards the sun, and towards each other; as well as the sun towards them; and that in proportion to the quantity of matter in each of them.

The Peripatetics &c hold, that bodies only gravitate or weigh when out of their natural places, and that gravita-

tion ceases when they are restored to the same, the purpose of nature being then fulfilled; and they maintain that the final cause of this faculty is only to bring elementary bodies to their proper place, where they may rest. But the moderns show that bodies exercise gravity even when at rest, and in their proper places. This is particularly shown of fluids; and it is one of the laws of hydrostatics, demonstrated by Boyle and others, that fluids gravitate in *proprio loco*, the upper parts pressing on the lower, &c.

For the laws of gravitation of bodies in fluids specifically lighter or heavier than themselves, see **SPECIFIC GRAVITY**. Also for the centre or line or plane of gravitation, see **CENTRE, LINE, OR PLANE**.

GRAVITY, in Physics, the natural tendency or inclination of bodies towards the centre. And in this sense gravity agrees with centripetal force.

Gravity however is, by some, defined more generally as the natural tendency of one body towards another; and again by others still more generally as the mutual tendency of each body, and each particle of a body, towards all others: in which sense the word answers to what is more usually called attraction. Indeed the terms gravity, weight, centripetal force, and attraction, denote in effect all the same thing, only in different views and relations; all which however it is very common to confound, and use promiscuously. But, in propriety, when a body is considered as tending towards the earth, the force with which it so tends is called Gravity, Force of Gravity, or Gravitating Force; when the body is considered as immediately tending to the centre of the earth, it is called Centripetal Force; but when we consider the earth, or mass to which the body tends, it is called Attraction, or Attractive Force; and when it is considered in respect of an obstacle or another body in the way of its tendency, on which it acts, it is called Weight.

Philosophers think differently on the subject of gravity. Some consider it as an inactive property or innate power in bodies, by which they endeavour to unite together. Others hold gravity in this sense to be an occult quality, and to be exploded as such out of all sound philosophy. Newton, though he often calls it a vis, power, or property in bodies, yet explains himself, that he means nothing more by the word but the effect or phenomenon: he does not consider the principle, the cause by which bodies tend downwards, but the tendency itself, which is no occult quality, but a sensible phenomenon, be its causes what they may; whether a property essential to body, as some make it, or superadded to it, as others; or even an impulse of some body from without, as others.

It is a law of nature long observed, that all bodies near the earth have a gravity or weight, or a tendency towards its centre, or at least perpendicular to its surface; which law the moderns, and especially Sir I. Newton, from certain observations, have found to be much more extensive, and holding universally with respect to all known bodies and matter in nature. It is therefore at present acknowledged as a principle or law of nature, that all bodies, and all the particles of all bodies, mutually gravitate towards each other: from which single principle it is that Newton has happily deduced all the great phenomena of nature. Hence, Gravity may be distinguished into Particular and General.

Particular Gravity, is that which respects the earth, or by which bodies descend, or tend towards the centre of the earth; the phenomena or properties of which are as follow:—

1. All circumterrestrial bodies do hereby tend towards a point, which is either accurately or very nearly the centre of magnitude of the terraqueous globe. Not that it is meant that there is really any virtue or charm in the point called the centre, by which it attracts bodies; but because this is the result of the gravitation of bodies towards all the parts of which the earth consists.

2. This point or centre is fixed within the earth, or at least has been so far as any authentic history reaches. For a consequence of its shifting, though ever so little, would be the overflowing of the low lands on that side of the globe towards which it should approach. Dr. Halley suggests, that it would well account for the universal deluge, to have the centre of gravitation removed for a time towards the middle of the then inhabited world; for the change of its place but the 2000th part of the radius of the earth, or about two miles, would be sufficient to lay the tops of the highest hills under water.

3. In all places equidistant from the centre of the earth the force of gravity is nearly equal. Indeed all parts of the earth's surface are not at equal distances from the centre, because the equatorial parts are higher than the polar parts by about 17 miles; as has been proved by the necessity of making the pendulum shorter in those places, before it will vibrate seconds. In the new Petersburg Transactions, vol. 6 and 7, M. Kraft gives a formula for the proportion of gravity in different latitudes on the earth's surface, which is this :

$$y = (1 + 0.0052848 \sin^2 \lambda) g;$$

where g denotes the gravity at the equator, and y the gravity under any other latitude λ . On this subject, see also the articles DEGREE, and EARTH.

4. Gravity equally affects all bodies, without regard either to their bulk, figure, or matter: so that, abstracting from the resistance of the medium, the most compact and loose, the greatest and smallest bodies, would all descend through an equal space in the same time; as appears from the quick descent of very light bodies in an exhausted receiver. The space which bodies do actually fall, in *vacuo*, is $16\frac{1}{2}$ feet in the first second of time, in the latitude of London; and for othertimes, either greater or less than that, the spaces descended from rest are directly proportional to the squares of the times, while the falling body is not far from the earth's surface.

5. This power is the greatest at the earth's surface, from whence it decreases both upwards and downwards, but not both ways in the same proportion; for upwards the force of gravity is less, or decreases, as the square of the distance from the centre increases, so that at a double distance from the centre, above the surface, the force would be only 1/4th of what it is at the surface; but below the surface, the power decreases in such sort that its intensity is in the direct ratio of the distance from the centre; so that at the distance of half a semidiiameter from the centre, the force would be but half what it is at the surface; at $\frac{1}{3}$ of a semidiiameter the force would be $\frac{2}{3}$, and so on.

6. As all bodies gravitate towards the earth, so does the earth equally gravitate towards all bodies; as well as all bodies towards particular parts of the earth, as hills, &c, which has been proved by the attraction a hill has upon a plumb line, insensibly drawing it aside.—Hence the gravitating force of entire bodies consists of those of all their parts: for, by adding or taking away any part of the matter of a body, its gravity is increased or decreased in the proportion of the quantity of such portion to the whole mass. Hence also the gravitating powers of bodies, at the

same distance from the centre, are proportional to the quantities of matter in the bodies.

General or Universal Gravity, is that by which not only the planets, but all the bodies and particles of matter in the universe tend towards one another. The existence of the same principle of gravitation in the superior regions of the heavens, as on the earth, is one of the great discoveries of Newton, who made the proof of it as easy as that on earth. At first it would seem this was only conjecture with him: he observed that all bodies near the earth, and in its atmosphere, had the property of tending directly towards it; he soon conjectured that it probably extended much higher than any distance to which we could reach, or make experiments; and so on, from one distance to another, till he at length saw no reason why it might not extend as far as the moon, by means of which she might be retained in her orbit, as a stone in a sling is retained by the hand; and if so, he next inferred, why might not a similar principle exist in the other great bodies in the universe, the sun and all the other planets, both primary and secondary, which might all be retained in their orbits, and perform their revolutions, by means of the same universal principle of gravitation.

These conjectures he soon realized and verified by mathematical proofs. Kepler had discovered by contemplating the motions of the planets about the sun, that the area described by a line connecting the sun and planet, as this revolved in its orbit, was always proportional to the time of its description, or that it described equal areas in equal times, in whatever part of its orbit the planet might be, moving always so much the quicker as its distance from the sun was less. And it is also found that the satellites, or secondary planets, observe the same law in revolving about their primaries. But it was soon proved by Newton, that all bodies moving in any curve line described on a plane, and which, by radii drawn to any certain point, describe areas about the point proportional to the times, are impelled or acted on by some power tending towards that point. Consequently the power by which all these planets revolve, and are retained in their orbits, is directed to the centre about which they move, viz, the primary planets to the sun, and the satellites to their several primaries.

Newton also demonstrated, that if several bodies revolve with an equable motion in several circles about the same centre, and that if the squares of their periodical times be in the same proportion as the cubes of their distances from the common centre, then the centripetal forces of the revolving bodies, by which they tend to their central body, will be in the reciprocal or inverse ratio of the squares of the distances. Or if bodies revolve in orbits approaching to circles, and the apses of those orbits be at rest, then also the centripetal forces of the revolving bodies will be reciprocally proportional to the squares of the distances. But it had been agreed on by astronomers, and particularly Kepler, that both these cases obtain in all the planets. And therefore he inferred, that the centripetal forces of all the planets, are reciprocally proportional to the squares of the distances from the centres of their motions.

On the whole it appears, that the planets are retained in their orbits by some power which is continually acting upon them: that this power is directed towards the centre of their motions: that the intensity or efficacy of this power increases on an approach towards the centre, and diminishes on receding from the same, and that in the re-

ciprocal duplicate ratio of the distances : and that, by comparing this centripetal force of the planets with the force of gravity on the earth, they are found to be perfectly alike, as may easily be shown in various instances. For example, in the case of the moon, the nearest of all the planets. The rectilinear spaces described in any given time by a falling body, urged by any powers, reckoning from the beginning of its descent, are proportional to those powers. Consequently the centripetal force of the moon revolving in her orbit, will be to the force of gravity on the surface of the earth, as the space which the moon would describe in falling during any small time, by her centripetal force towards the earth, if she had no circular motion at all, to the space a body near the earth would describe in falling by its gravity towards the same.

Now by an easy calculation of those two spaces, it appears that the former force is to the latter, as the square of the semi-diameter of the earth is to the square of that of the moon's orbit. The moon's centripetal force therefore is equal to the force of gravity ; and consequently these forces are not different, but they are one and the same : for if they were two distinct forces, bodies acted on by the two powers conjointly would fall towards the earth with a velocity double to that arising from the sole power of gravity.

It is evident therefore that the moon's centripetal force, by which she is retained in her orbit, and prevented from flying off in tangents, is the very power of gravity of the earth extended thither. See Newton's Princip. lib. 1, prop. 45, cor. 2, and lib. 3, prop. 3 ; where the numeral calculation may be seen at full length.

The moon therefore gravitates towards the earth, and reciprocally the earth towards the moon. And this is also further confirmed by the phenomena of the tides.

The like reasoning may also be applied to the other planets. For, as the revolutions of the primary planets round the sun, and those of the satellites of Jupiter and Saturn round their primaries, are phenomena of the same kind with the revolution of the moon about the earth ; and as the centripetal powers of the primary are directed towards the centre of the sun, and those of the satellites towards the centres of their primaries ; and lastly, as all these powers are reciprocally as the squares of the distances from the centres, it may safely be concluded that the power and cause are the same in all.

Therefore, as the moon gravitates towards the earth, and the earth towards the moon ; so doall the secondaries to their primaries, and these to their secondaries ; and so also do the primaries to the sun, and the sun to the primaries. Newton's Princip. lib. 3, prop. 4, 5, 6; Greg. Astron. lib. 1, sect. 7, prop. 46 and 47.

The laws of Universal Gravity are the same as those of bodies gravitating to the earth, before laid down.

Cause of Gravity. Various theories have been advanced by the philosophers of different ages to account for this grand principle of gravitation. The ancients, who were only acquainted with particular gravity, or the tendency of sublunar bodies towards the earth, aimed no further than a system that might answer the more obvious phenomena of it. However, some hints are found concerning the gravitation of celestial bodies, in the account given of the doctrine of Thales and his successors ; and it would seem that Pythagoras was still better acquainted with it, to which it is supposed he had a view in what he taught concerning the Harmony of the Spheres.

Aristotle and the Peripatetics content themselves with

referring gravity or weight to a native inclination in heavy bodies to be in their proper place or sphere, the centre of the earth. And Copernicus ascribes it to an innate principle in all parts of matter, by which, when separated from their wholes, they endeavour to return to them again the nearest way. In answer to Aristotle and his followers, who considered the centre of the earth as the centre of the universe, he observed that it was reasonable to think there was nothing peculiar to the earth in this principle of gravity : that the parts of the sun, moon, and stars, tended likewise to each other, and that their spherical figure was preserved in their various motions by this power. Copern. Revol. lib. 1, cap. 9. But neither of these systems assigns any physical cause of this great effect : they only amount to this, that bodies descend because they are inclined to descend.

Kepler, in his preface to the commentaries concerning the planet Mars, speaks of gravity as of a power that was mutual between bodies, and says that the earth and moon tend towards each other, and would meet in a point so many times nearer to the earth than to the moon, as the earth is greater than the moon, if their motions did not hinder it. He adds, that the tides arise from the gravity of the waters towards the moon. To him we also owe the important discovery of the analogy between the distances of the several planets from the sun, and the periods in which they complete their revolutions, viz, that the squares of their periodic times, are always in the same proportion as the cubes of their mean distances from the sun. However, Kepler, Gassendi, Gilbert, and others, ascribe gravity to a certain magnetic attraction of the earth ; conceiving the earth to be one great magnet, continually emitting effluvia, which take hold of all bodies, and draw them towards the earth. But this is inconsistent with the several phenomena.

Descartes and his followers, Rohault, &c, attribute gravity to an external impulse or trusion of some subtle matter. By the rotation of the earth, say they, all the parts and appendages of it necessarily endeavour to recede from the centre of rotation ; but whence they cannot all actually recede, as there is no vacuum or space to receive them. But this hypothesis, founded on the supposition of a plenum, is overthrown by what has been since proved of the existence of a vacuum.

Dr. Hooke inclines to an opinion much like that of Descartes. Gravity he thinks deducible from the action of a most subtle medium, which easily pervades and penetrates the most solid bodies ; and which, by some motion it has, detrudes all earthly bodies from it, towards the centre of the earth. Vossius too, and many others, give partly into the Cartesian notion, and suppose gravity to arise from the diurnal rotation of the earth round its axis. See Birch's Hist. of the Royal Soc. vol. 2, pp. 72 and 91.

Dr. Halley, despairing of any satisfactory theory, chooses to have immediate recourse to the agency of the Deity. So Dr. Clarke, from a view of several properties of gravity, concludes that it is no adventitious effect of any motion, or subtle matter, but an original and general law impressed by God on all matter, and preserved in it by some efficient power penetrating the very solid and intimate substance of it ; being found always proportional, not to the surfaces of bodies or corpuscles, but to their solid quantity and contents. It should therefore be no more inquired why bodies gravitate, than how they came to be first put in motion. Annot. in Rohault. Phys. part 1, cap. 11.

Gravesande, in his *Introduct.* ad Philos. Newton. contends that the cause of gravity is utterly unknown; and that we are to consider it no otherwise than as a law of nature originally and immediately impressed by the Creator, without any dependence on any second law or cause at all. Of this he thinks the three following considerations sufficient proof. 1. That gravity requires the presence of the gravitating or attracting body: so the satellites of Jupiter, for ex. gravitate towards Jupiter, wherever he may be. 2. That the distance being supposed the same, the velocity with which bodies are moved by the force of gravity, depends on the quantity of matter in the attracting body; and the velocity is not changed, whatever the mass of the gravitating body may be. 3. That if gravity do depend on any known law of motion, it must be some impulse from an extraneous body; so that as gravity is continual, a continual stroke must also be required. Now if there be any such matter continually striking on bodies, it must be fluid, and subtle enough to penetrate the substance of all bodies: but how shall a body subtle enough to penetrate the substance of the hardest bodies, and so rare as not sensibly to hinder the motion of bodies, be able to impel vast masses towards each other with such force? how does this force increase the ratio of the mass of the body, towards which the other body is moved? whence is it that all bodies move with the same velocity, the distance and body gravitated to being the same? can a fluid which only acts on the surface, either of the bodies themselves, or their internal particles, communicate such a quantity of motion to bodies, which in all bodies shall exactly follow the proportion of the quantity of matter in them?

Mr. Cotes goes yet further. Giving a view of Newton's philosophy, he asserts that gravity is to be ranked among the primary qualities of all bodies; and deemed equally essential to matter as extension, mobility, or impenetrability. Prefat. ad Newt. Princip. But Newton himself disclaims this notion; and to show that he does not take gravity to be essential to bodies, he declares his opinion of the cause; choosing to propose it by way of query, not being yet sufficiently satisfied about it for want of experiments. Thus, after having shown that there is a medium in nature vastly more subtle than air, by whose vibrations sound is propagated, by which light communicates heat to bodies, and by the different densities of which the refraction and reflection of light are performed; he proceeds to inquire: "Is not this medium much rarer within the dense bodies of the sun, stars, planets, and comets, than in the empty celestial spaces between them? and in passing from them to greater distances, doth it not grow denser and denser perpetually, and thereby cause the gravity of those great bodies towards one another, and of their parts towards the bodies; every body endeavouring to recede from the denser parts of the medium towards the rarer?"

"For if this medium be supposed rarer within the sun's body than at its surface, and rarer there than at the hundredth part of an inch from his body, and rarer there than at the orbit of Saturn; I see no reason why the increase of density should stop any where, and not rather be continued through all distances from the sun to Saturn, and beyond."

"And though this increase of density may at great distances be exceeding slow: yet if the elastic force of this medium be exceeding great, it may suffice to impel bodies

from the denser parts of the medium towards the rarer with all that power which we call gravity."

"That the elastic force of this medium is exceeding great, may be gathered from the swiftness of its vibrations. Sounds move about 1140 English feet in a second of time, and in seven or eight minutes of time, they move about one hundred English miles: light moves from the sun to us in about 7 or 8 minutes of time, which distance is about 70000000 English miles, supposing the horizontal parallax of the sun to be about 12 seconds; and the vibrations, or pulses of this medium, that they may cause the alternate fits of easy transmission, and easy reflection, must be swifter than light, and by consequence above 700000 times swifter than sounds; and therefore the elastic force of this medium, in proportion to its density, must be above 700000×700000 (that is, above 490000000000) times greater than the elastic force of the air is, in proportion to its density: for the velocities of the pulses of elastic mediums, are in a subduplicate ratio of the elasticities and the rarities of the mediums conjointly.

"As magnetism is stronger in small loadstones than in great ones, in proportion to their bulk; and gravity is stronger on the surfaces of small planets, than on those of great ones, in proportion to their bulk; and small bodies are agitated much more by electric attraction than great ones: so the smallness of the rays of light may contribute very much to the power of the agent by which they are refracted; and if any one should suppose, that ether (like our air) may contain particles which endeavour to recede from one another (for I do not know what this ether is), and that its particles are exceedingly smaller than those of air, or even than those of light; the exceeding smallness of such particles may contribute to the greatness of the force, by which they recede from one another, and thereby make that medium exceedingly more rare and elastic than air, and, of consequence, exceedingly less able to resist the motions of projectiles, and exceedingly more able to press upon gross bodies by endeavouring to expand itself." Optics, Query 21, &c.

M. Le Sage attempts to account for the cause of gravity by the following ingenious hypothesis: "Imagine," says this author, "that through all space numberless corpuscles or atoms, almost infinitely small, are in perpetual motion: that every corpuscle has its determined direction, and moves for ever in a straight line with a velocity far exceeding that of light. It is evident that the directions of these corpuscles may be so various, they may be themselves so small, and their velocity so great, that though they follow each other at vast distances, and leave space, in reality, almost empty; yet they may abound every where in such a manner, that in a portion of time, almost infinitely small, a great number of them shall pass through every point of space whatsoever. On whatever point of space therefore our attention is fixed, we may consider it as a centre, to which the motions of an infinite number of atoms are referred, either by diverging therefrom, or converging to it." This constitution of what Le Sage calls the gravific fluid being conceived, suppose a solid body to be plunged into it of any figure whatever, larger than one of the corpuscles, and in some degree, if not entirely, impervious to these particles; this body will remain at rest, or at least without any progressive motion, the impulses of the particles that strike against it being equal in opposite directions. It may oscillate a little backward

and forward, but will not be forced any considerable distance from its place.

Now let there be plunged into the gravific fluid, another body, of any figure, and at any distance from the first. These two bodies will immediately begin to move towards each other. For the one serving to protect the other from a certain quantity of the impulsion of the corpuscles, the currents thus left without opposition necessarily produce their effect, and impel the bodies towards each other.

Their motion towards one another will be continually accelerated; and the forces producing that acceleration will increase in proportion as the one body stops more of the currents from falling on the other; that is, nearly as the squares of the distances diminish.

Again, if the solid particles of which the bodies are made up, be impenetrable to the gravific corpuscles, but the bodies themselves, on account of their porosity, permeable by them in a certain degree, the number of particles that are stopped by each of the bodies will be, ceteris paribus, proportional to the number of solid particles, that is, to the quantities of matter in the bodies; and hence, in general, the force urging the bodies towards each other, will be directly as their masses, and inversely as the squares of their distances. "Thus, by mechanical action," says Le Sage, "is the Newtonian law of gravitation explained in all its parts."

In objection to this system, we advance the following, urged by Boscovich:—"In this system," says Boscovich, "no particle of the fluid returns to its place, or ever passes a second time through the same point of space. A constant supply of new particles is therefore necessary, as all those that are contained within the limits of the sensible universe, at any instant, must be replaced before they have entirely escaped from it, and sent forth to traverse for ever the deserts of uninhabited extension. The imagination is terrified at this constant exertion of what cannot be considered as less than creative power employed in producing existencies that, for a limited time, are to be useful; and through all the rest of infinite duration, are to serve no purpose whatsoever."

About the year 1806 several of the clergy, as well as other individuals in this country, being alarmed, it was said, at the efforts which the philosophers on the continent were making to account for the various operations of nature upon mere mechanical principles, with a view, as they supposed, to exclude the Deity from any concern in the government of the world, and thereby to lay a foundation for atheism, Mr. Vince, professor of astronomy in the university of Cambridge, was requested to examine the most plausible and generally received hypotheses, which had been framed to account for gravitation, and to give the result of his examination. The inquiry, he tells us, was favourably received, and it was suggested that it might not be improper to offer it to the Royal Society; but on being presented by his friend Dr. Maskelyne, the astronomer-royal, and not meeting that reception which would have been gratifying to the professor's feelings, and have reflected credit on the Society, he in consequence withdrew it, and submitted the paper to the opinion of the public, in a small pamphlet on this subject, printed at Cambridge, in 1806.

The systems which he has there considered, are those of Descartes, Newton, Le Sage, and Bernoulli, with a slight mention of some others whose inconsistency ren-

dered any detailed account of them unnecessary, but omitting that of Boscovich.

Speaking of the system of Saussure, (which, by the bye, is that of Le Sage, given above,) he observes, that if the corpuscles there mentioned be admitted to move as the author describes them, it will follow that the moving force of each body depends on the surfaces of the bodies, whereas it ought to be as the quantity of matter in each respectively: "this consideration, therefore," continues the professor, "without entering into any further examination of the hypothesis, is sufficient to show that it cannot be admitted."

The hypothesis which Mr. Vince has made the subject of mathematical consideration, is that of our illustrious countryman Newton; who, as has been observed, supposed, that if the sun and the planets acted on each other, it must be by some intermediate and invisible substance, such as that of an elastic fluid. The professor then admitting that an elastic fluid is the cause of gravity, lays down, previous to the estimation of its effects on bodies placed in it, the two following facts, as standards, to which his results are to be referred for refutation or support:

1. That the gravitation of a planet varies inversely as the square of its distance from the sun; that is, whatever be the magnitude or density of the planet, its acceleration towards the sun varies in that ratio.

2. That a force varying inversely as the square of the distance, cannot be compounded of several forces, each of which does not vary in that ratio.

On these grounds, the professor enters on the investigation of the hypothesis; by supposing that the density of the medium is measurable by the number of particles, uniformly diffused on a given square area; that the variation of density at any distance d , from the sun is as d^m ; and consequently the distance of the particles themselves as $\frac{1}{d^{\frac{m}{2}}}$. Then, admitting that the elastic force of the par-

ticles vary as the n th power of their distance, or as $\frac{1}{d^{\frac{mn}{2}}}$, he at last obtains $\frac{2m - mn}{3e} \times a^{\frac{2m - mn}{n}} - 1$, for the accelerative force of the planet towards the sun at the distance a from the same.

"Now it is to be observed," says Mr. Vince, "that this expression is in terms of e , the density of the planet; and therefore does not agree with the first given fact or law of gravitation, that law being independent of the density or magnitude. Therefore in this case, the hypothesis is rendered nugatory."

But besides this, he states that the body will, instead of being forced towards the sun, be driven from it, even when the force varies inversely as the square of the distance. Hence, and from what is afterwards demonstrated, he concludes, that it is not possible for any law of variation of density, of the fluid, in terms of the distance from the sun, combined with any law of variation of the repulsive force of the particles of the fluid in terms of their distance, which can satisfy the law of gravitation. And if we were to suppose the law of density to vary in terms of any other quantities besides those expressing the distance from the sun, such quantities must enter into the law of force, and thereby make a still greater deviation from the law of the inverse square of the distance. Considering the matter therefore, in a mathematical point of view, we

are justified, he says, in rejecting this hypothesis as the cause of gravitation.

Mr. Playfair however, in reviewing this examination, observes that, this conclusion he (Mr. Vince) next endeavours to extend to all the laws of variation of density and of elasticity that can possibly exist, by showing that no one can be admitted that is not capable of being expressed by a single term, and consequently by the m th or n th power of the distance. It is here, if we mistake not, that the error lies. For, though a variation of density or of elasticity, expressed thus, $ax^m + bx^n$, cannot take place, because the force arising from it would also involve two terms, yet if one of the terms be constant, as if $m = 0$, and so the expression $= a + bx^n$, then the force would be expressed by one term only, viz, by the fluxion of bx^n , that is, by a quantity proportional to x^{n-1} . Thus, for example, if x be any distance from the sun's centre, d the density of the ether at that distance, and e its elasticity. Let d increase in the direct ratio of x , or $d = ax$; and suppose $e = c - \frac{1}{d} = c - \frac{1}{ax}$, where c is a constant quantity, that would be determined, if we knew at what distance from the sun's centre the elasticity of the ether is $= 0$. If, for example, it is equal to nothing at the distance s from the sun's centre, or when $x = s$, $c = \frac{1}{as}$, so that $e = \frac{1}{as} - \frac{1}{ax}$, and the differential of this being taken, gives $\dot{e} = \frac{\dot{x}}{ax^2}$. Now \dot{e} is the difference of elasticity for the change of distance \dot{x} ; and therefore is the force with which a small spherical body, or a single particle of matter, impervious to the ether, would be impelled toward the sun; and it varies as $\frac{1}{x^2}$, or in the inverse ratio of the squares of the distances from the sun. It is therefore possible that an elastic fluid may be so constituted as to produce a tendency of one body to another, varying inversely as the squares of the distances of these bodies.—For this purpose, there is only required an elastic fluid, of which the density is as the distance from the sun, and the elasticity as a certain given magnitude diminished by the reciprocal of that distance. There are many other hypotheses concerning the density and elasticity of the fluid, which will give the same result with this; all indeed in which we have these equations, $d = ax^m$, and $e = c - \frac{1}{d^m}$. This

is directly contrary to Mr. Vince's conclusion, "that it is not possible for any law of variation of the density of the fluid in terms of the distance from the sun, combined with any law of variation of the repulsive force of the particles of the fluid in terms of their distance, to satisfy the law of gravitation." See the Edinburgh Review, vol. 13, pa. 101, &c.

GRAVITY, in Mechanics, denotes the conatus or tendency of bodies towards the centre of the earth. That part of mechanics which considers the equilibrium or motion of bodies arising from gravity or weight, is particularly called Statics.

Gravity is distinguished into absolute and relative.

Absolute GRAVITY is that with which a body descends freely and perpendicularly through an unresisting medium. The laws of which see under DESCENT OF BODIES, ACCELERATION, MOTION, &c.

Relative GRAVITY is that with which a body descends

on an inclined plane, or through a resisting medium, or as opposed by some other resistance. The laws of which, see under the articles INCLINED PLANE, DESCENT, FLUID, RESISTANCE, &c.

GRAVITY, in Hydrostatics. The laws of bodies gravitating in fluids constitute the doctrine of Hydrostatics.

Gravity is here divided into absolute and specific.

Absolute or True GRAVITY, is the whole force with which the body tends downwards.

Specific GRAVITY, is the relative, comparative, or apparent gravity in any body, in respect of that of an equal bulk or magnitude of another body; denoting that gravity or weight which is peculiar to each species or kind of body, and by which it is distinguished from all other kinds.

In this sense a body is said to be specifically heavier than another, when under the same bulk it contains a greater weight than that other; and reciprocally, the latter is said to be specifically lighter than the former. Thus, if there be two equal spheres, each one foot in diameter; the one of lead, and the other of wood: since the leaden one is found heavier than the wooden one, it is said to be specifically, or in specie, heavier; and the wooden one specifically lighter.

This kind of gravity is by some called relative; in opposition to absolute gravity, which increases in proportion to the quantity or mass of the body.

Laws of the SPECIFIC GRAVITY of Bodies.

I. If two bodies be equal in bulk, their specific gravities are to each other as their weights, or as their densities.

II. If two bodies be of the same specific gravity or density, their absolute weights will be as their magnitudes or bulks.

III. In bodies of the same weight, the specific gravities are reciprocally as their bulks.

IV. The specific gravities of all bodies are in a ratio compounded of the direct ratio of their weights, and the reciprocal ratio of their magnitudes. And hence again the specific gravities are as the densities.

V. The absolute gravities or weights of bodies are in the compound ratio of their specific gravities and magnitudes or bulks.

VI. The magnitudes of bodies are directly as their weights, and reciprocally as their specific gravities.

VII. A body specifically heavier than a fluid, loses as much of its weight, when immersed in it, as is equal to the weight of a quantity of the fluid of the same bulk or magnitude.—Hence, since the specific gravities are as the absolute gravities under the same bulk; the specific gravity of the fluid, will be to that of the body immersed, as the part of the weight lost by the solid, is to the whole weight. And hence the specific gravities of fluids, are as the weights lost by the same solid immersed in them.

VIII. To find the Specific Gravity of a Fluid, or of a Solid.—On one arm of a balance suspend a globe of lead by a fine thread, and to the other fasten an equal weight, which may just balance it in the open air. Immerse the globe into the fluid, and observe what weight balances it then, and consequently what weight is lost, which is proportional to the specific gravity as above. And thus the proportion of the specific gravity of one fluid to another, is determined by immersing the globe successively in all the fluids, and observing the weights lost in each, which will be the proportions of the specific gravities of the fluids sought.

This same operation determines also the specific gravity of the solid immersed, whether it be a globe or of any other shape or bulk, supposing that of the fluid known. For the specific gravity of the fluid is to that of the solid, as the weight lost is to the whole weight. Hence also may be found the specific gravity of a body that is lighter than the fluid, as follows :

IX. To find the Specific Gravity of a Solid that is lighter than the fluid, as water, in which it is placed.—Annex to the lighter body another that is much heavier than the fluid, so as the compound mass may sink in the fluid. Weigh the heavier body and the compound mass separately, both in water and out of it; then find how much each loses in water, by subtracting its weight in water from its weight in air; and subtract the less of these remainders from the greater. Then say,

As this last remainder,

As this last remainder,
Is to the weight of the light body in air,

So is the specific gravity of the fluid,

To the specific gravity of that body.

X. The specific gravities of bodies of equal weight, are reciprocally proportional to the quantities of weight lost in the same fluid. And hence is found the ratio of the specific gravities of solids, by weighing in the same fluids, masses of them that weigh equally in air, and noting the weights lost by each.

The specific gravities of many kinds of bodies, both solid and fluid, have been determined by various authors. Marinus Ghetaulus particularly tried the specific gravities of various bodies, especially metals; which were taken from thence by Oughtred. In the Philos. Trans. are several ample tables of them, by various authors, particularly those of Mr. Davis, vol. 45, pa. 416. Some tables of them were also published by P. Mersenne, Muschenbroeck, Ward, Cotes, Emerson, Martin, &c.

The following table, taken chiefly from Gregory's excellent book of Mechanics, contains the specific gravities of most of the principal bodies, both solid and fluid. The numbers express the avoirdupois ounces in a cubic foot of each body, that of distilled water being just 1000 ounces, which is here made the standard of comparison of all the rest.

TABLE of the SPECIFIC GRAVITIES of Different Bodies.

L. Metals.

I. Metals.								
Antimony, crude	-	-	-	4064	. . .	French coin	-	10408
. . . glass of	-	-	-	4946	. . .	Tin, pure Cornish, melted, and not hardened	-	7291

Lard	-	948	For the Weight and Specific Gravities of the different Gases, see the article GAS.					
Mastic	-	1074	These numbers being the weight of a cubic foot, or 1728 cubic inches, of each of the bodies, in avoirdupois ounces, by proportion the quantity in any other weight, or the weight of any other quantity, may be readily known.					
Myrrh	-	1360	For Example. Required the content of an irregular block of common stone which weighs 1 cwt, or 112lb, or 1792 ounces. Here, as 2500 : 1792 :: 1728 : 1228 $\frac{1}{2}$ cubic inches the content.					
Opium	-	1336	Example 2. To find the weight of a block of granite, whose length is 63 feet, and breadth and thickness each 12 feet; being the dimensions of one of the stones, of granite, in the walls of Balbeck. Here, $63 \times 12 \times 12 = 9072$ feet is the content of the stone; therefore as 1 : 9072 :: 3000 oz. : 27216000 oz. or 759 tons 7 cwt. 2 qrs. the weight of the stone.					
Scammony. See Gum.	-	845	XI. A body descends in a fluid specifically lighter, or ascends in a fluid specifically heavier, with a force equal to the difference between its weight and that of an equal bulk of the fluid.					
Serum of human blood	-	800	XII. A body sinks in a fluid specifically heavier, so far as that the weight of the body is equal to the weight of a quantity of the fluid of the same bulk as the part immersed. Hence, as the specific gravity of the fluid is to that of the body, so is the whole magnitude of the body, to the magnitude of the part immersed.					
Spermaceti	-	793	XIII. The specific gravities of equal solids, are as their parts immersed in the same fluid.					
Storax	-	845	The several theorems here delivered, are both demonstrable from the principles of mechanics, and are also equally conformable to experiment, which answers exactly to the calculation; as is abundantly evident from the courses of philosophical experiments, so frequently exhibited; where the laws of specific gravitation are well illustrated.					
Tallow	-	822	GREAT BEAR, one of the constellations in the northern hemisphere. See URSA MAJOR.					
Terra Japonica	-	852	GREAT CIRCLES, of the Globe or Sphere, are those whose planes pass through the centre, dividing it into two

equal parts or hemispheres, and therefore having the same centre and diameter with the sphere itself. The principal of these are, the equator, the ecliptic, the horizon, the meridians, and the two colures.

GREAT-CIRCLE SAILING, is the art of conducting a ship along the arc of a great circle. And it is also that part of the theory of navigation which treats of sailing in the arc of a great circle. See **NAVIGATION**.

GREAVES (JOHN), an eminent astronomer, antiquary, and linguist, was born in 1602, being the eldest son of John Greaves, rector of Colemore, near Alresford in Hampshire, and master of a grammar-school, where his son of course was well grounded in the primary rules of literature. He then went to Balliol-college, Oxford, in 1617; but afterwards, on account of his skill in philosophy and polite literature, he was the first of five that were elected into Merton-college. Having read over all the ancient Greek and Latin writers, he applied to the study of natural philosophy and mathematics; and having contracted an intimacy with Mr. Briggs, Savilian professor of geometry at Oxford, and Dr. Bainbridge, Savilian professor of astronomy there, he was animated by their examples to prosecute that study with the greatest industry. Not being content, however, with reading the writings of Purbach, Regiomontanus, Copernicus, Tycho Brahe, Kepler, and other celebrated astronomers of that and the preceding age, he made the ancient Greek, Arabian, and Persian authors familiar to him, having before gained an accurate skill in the oriental languages. These accomplishments procured him the professorship of geometry in Grey-sham-college London, in 1630; and at the same time he held his fellowship of Merton-college.

In a journey to the continent, in 1635, he visited the celebrated Golius, professor of Arabic at Leyden, and Claud Hardy at Paris, to converse about the Persian language. Hence he passed through Italy, and accurately surveyed the venerable remains of antiquity at Rome, visiting and corresponding everywhere with the most learned men of every nation. After visiting Padua, Florence, and Leghorn, he hence embarked for Constantinople, where he arrived in 1638. Thence he passed over to Rhodes, and Alexandria in Egypt, where he staid four or five months, and made a great number of curious observations. He next went to Grand Cairo, and measured the pyramids; and while there he adjusted the measure of the foot, observed by all nations. Hence he returned again through Italy, and arrived in England in the year 1640, having stored his mind with a variety of curious knowledge, and collected many valuable oriental manuscripts and ancient curiosities. While at Rome he made a particular inquiry into the true state of the ancient weights and measures.

On the death of Dr. John Bainbridge, in 1643, he was chosen Savilian professor of astronomy at Oxford, and principal reader of Linacre's lecture in Merton-college; an appointment for which he was eminently qualified, from his critical acquaintance with the works of the ancient and modern astronomers. In 1645 he proposed a method of reforming the calendar, by omitting the intercalary day for 40 years to come: the paper relating to which, was published by Dr. Thomas Smith, in the Philos. Trans. for 1699. In 1646, he published his *Pyramidographia*, or a Description of the Pyramids of Egypt; and, in 1647, his Discourse on the Roman Foot and Denarius; from which, as from two principles, the measures and weights used by

the ancients may be deduced. He also published several curious works concerning antiquities, &c.

Soon after publishing the last-mentioned book, he was ejected, by the parliament visitors, from the professorship of astronomy and fellowship of Merton-college; when the soldiers committed many outrages, breaking open his chests, and destroying many of his manuscripts; which greatly affected him. On this occasion he retired to London, where he afterwards married, and prosecuted his studies with great vigour, as appears from several of his philosophical and theological writings. This however proved but a transient happiness to him; for he died at London, the 8th of October 1652, before he was quite 50 years of age; and left his astronomical instruments to the Savilian library in Oxford, where they are deposited.

GREEK ORDERS, in Architecture, are the Doric, Ionic, and Corinthian; in contradistinction to the two Latin orders, viz the Tuscan and Composite.

GREEN, one of the original colours of the rays of light, or of the prismatic colours exhibited by the refraction of the rays of light. This is the pleasantest of all the colours to the sight. And hence it has been inferred as a proof of the wisdom and goodness of the Deity, that almost all vegetables, clothing the surface of the earth, are green; which they are when growing in the open air; though those in subterraneous places, or places inaccessible to fresh air, are white or yellow. See **CHROMATICS**, and **COLOURS**.

GREGORIAN CALENDAR, so called from Pope Gregory the 13th, is the new or reformed calendar, showing the new and full moons, with the time of Easter, and the other moveable feasts depending on it, by means of epacts disposed through the several months of the Gregorian year.

GREGORIAN Epoch, is the epoch or time, from which the Gregorian calendar, or computation, took place. This began in the year 1582; so that the year 1800 is the 218th of this epoch.

GREGORIAN Telescope, a particular kind of telescope, invented by Mr. James Gregory. See **TELESCOPE**.

GREGORIAN Year, the new account, or new style, introduced on the reformation of the calendar, by Pope Gregory the 13th, in the year 1582, and from whom it took its name. This was introduced to reform the old, or Julian year, established by Julius Caesar, which consisted of 365 days 6 hours, or 365 days and a quarter, that is three years of 365 days each, and the fourth year of 366 days. But as the mean tropical year consists only of 365d. 5hrs. 48m. 57sec. the former lost 11min. 3sec. every year, which in the time of Pope Gregory had amounted to 10 days, and who, by adding these 10 days, brought the account of time to its proper day again, and at the same time appointed that every century after, a day more should be added, thereby making the years of the complete centuries, viz, the 17th, 18th, 19th, 21st, which are not exactly divisible by 4, &c, to be common years of 365 days each, instead of leap-years of 366 days, which makes the mean Gregorian year equal to 365d. 5hrs. 45m. 36sec.

This computation was not introduced into the account of time in England, till the year 1752, when the Julian account had lost 11 days, and therefore the 3d of September was in that year, by act of parliament, accounted the 14th, thereby restoring the 11 days which had thus been omitted. See **YEAR**.

GREGORY (JAMES), one of the most celebrated ma-

thematicians of the 17th century, was the son of the Rev. John Gregory, minister of Drumoak in the county of Aberdeen, and born at Aberdeen in November 1638 or -9. His mother was a daughter of Mr. David Anderson of Finzaugh, or Finshaugh, a gentleman who possessed a singular turn for mathematical and mechanical knowledge. This mathematical genius was hereditary in the family of the Andersons, and from them it appears to have been transmitted to their descendants of the names of Gregory, Reid, &c. Alexander Anderson, cousin-german of the said David, was professor of mathematics at Paris in the beginning of the 17th century, and published there several valuable and ingenious works; as may be seen in the memoirs of his life and writings, under the article ANDERSON. The mother of James Gregory inherited the genius of her family; and observing in her son, while yet a child, a strong propensity to mathematics, she instructed him herself in the elements of that science. His education in the languages he received at the grammar-school of Aberdeen, and went through the usual course of academical studies in the Marischal college; but he was chiefly delighted with philosophical researches, into which a new door had lately been opened by the key of the mathematics. Galileo, Kepler, Descartes, &c, were the great masters of this new method: their works therefore became the principal study of young Gregory, who soon began to make improvements on their discoveries in Optics. The first of these improvements was the invention of the reflecting telescope; the construction of which instrument he published in his *Optica Promota*, in 1663, at 24 years of age. This discovery soon attracted the attention of the mathematicians, both of our own and of foreign countries, who immediately perceived its great importance to the sciences of optics and astronomy. But the manner of placing the two specula on the same axis appearing to Newton to be attended with the disadvantage of losing the central rays of the larger speculum, he proposed an improvement on the instrument, by giving an oblique position to the smaller speculum, and placing the eye-glass in the side of the tube. It is observable, however, that the Newtonian construction of that instrument was long abandoned for the original or Gregorian, which is now always used when the instrument is of a moderate size; though Herschel has preferred the Newtonian form for the construction of those immense telescopes, which he has of late so successfully employed in observing the heavens.

About the year 1664 or 1665, coming to London, he became acquainted with Mr. John Collins, who recommended him to the best optic glass-grinders there, to have his telescope executed. But as this could not be done for want of skill in the artists to grind a plate of metal for the object-speculum into a true parabolic concave, which the design required, he was much discouraged with the disappointment; and after a few imperfect trials made with an ill-polished spherical one, which did not succeed to his wish, he gave up the pursuit, and resolved to make the tour of Italy, then the mart of mathematical learning, that he might prosecute his favourite study with greater advantage. And the university of Padua being at that time in high reputation for mathematical studies, Mr. Gregory fixed his residence there for some years. Here it was that he published, in 1667, *Vera Circuli et Hyperbolae Quadratura*; in which he propounded another discovery of his own, the invention of an infinitely converging series for the areas of the circle and hyperbola. He sent to

England a copy of this work to his friend Mr. Collins, who communicated it to the Royal Society, where it met with the commendations of Lord Brouncker and Dr. Wallis. He reprinted it at Venice the year following, to which he added a new work, entitled *Geometriae Pars Universalis, inserviens Quantitatum Curvarum Transmutationi et Mensurae*; in which he is allowed to have shown, for the first time, a method for the transmutation of curves. These works engaged the notice, and procured the author the correspondence, of the greatest mathematicians of the age, Newton, Huygens, Wallis, and others. An account of this piece was also read by Mr. Collins before the Royal Society, of which Mr. Gregory, being returned from his travels, was chosen a member the same year, and communicated to them an account of a controversy in Italy about the motion of the earth, which was denied by Riccioli and his followers.—Through this channel, in particular, he carried on a dispute with Mr. Huygens on the occasion of his treatise on the quadrature of the circle and hyperbola, to which that great man had started some objections; in the course of which our author produced some improvements of his series. But in this controversy it happened, as it generally does on such occasions, that the antagonists, though setting out with proper coolness, yet grew too warm in the combat. This was the case here, especially on the side of Gregory, whose defence was, at his own request, inserted in the Philosophical Transactions. It is unnecessary to enter into particulars: suffice it therefore to say, that, in the opinion of Leibnitz, who allows Mr. Gregory the highest merit for his genius and discoveries, M. Huygens has pointed out, though not errors, some considerable deficiencies in the treatise above mentioned, and shown a much simpler method of attaining the same end.

In 1668, our author published at London another work, entitled, *Exercitationes Geometricæ*, which contributed still much farther to extend his reputation. About this time he was elected professor of mathematics in the university of St. Andrews, an office which he held for six years. During his residence there, he married, in 1669, Mary, the daughter of George Jameson, the celebrated painter, whom Mr. Walpole has termed the Vandyke of Scotland, and who was fellow-disciple with that great artist in the school of Rubens at Antwerp.

In 1672, he published *The Great and New Art of weighing Vanity: or a Discovery of the Ignorance and Arrogance of the Great and New Artist*, in his Pseudo-philosophical Writings. By M. Patrick Mathers, archdean to the University of St. Andrews. To which are annexed some *Tentamina de Motu Penduli et Projectorum*. Under this fictitious name, our author wrote this little piece to expose the pretended ignorance of Mr. Sinclair, professor at Glasgow, in his hydrostatical writings, and in return for some alleged ill usage of that author to a colleague of Mr. Gregory's. The same year, Newton, on his wonderful discoveries in the nature of light, contrived a new reflecting telescope, and made several objections to Mr. Gregory's. This gave birth to a dispute between those two philosophers, which was carried on during this and the following year, in the most amicable manner on both sides; Mr. Gregory defending his own construction, so far, as to give his antagonist the whole honour of having made the catoptric telescopes preferable to the dioptric; and showing, that the imperfections in these instruments were not so much owing to a defect in

the object-speculum, as to the different refrangibility of the rays of light. In the course of this dispute, our author described a burning concave mirror, which was approved by Newton, and is still in good esteem. Several letters that passed in this dispute, are printed by Dr. Desaguliers, in an Appendix to the English edition of Dr. David Gregory's Elements of Catoptrics and Dioptrics.

In 1674, Mr. Gregory was called to Edinburgh, to fill the chair of mathematics in that university. This place he had held but little more than a year, when, in October 1675, being employed in showing the satellites of Jupiter through a telescope to some of his pupils, he was suddenly struck with total blindness, and died a few days after, to the great loss of the mathematical world, at only 36 years of age.

As to his character, Mr. James Gregory was a man of a very acute and penetrating genius. His temper was in some degree an irritable one, as appears from his conduct in the dispute with Huygens; and, conscious perhaps of his own merits as a discoverer, he seems to have been jealous of losing any portion of his reputation by the im-provements of others upon his inventions. He possessed one of the most amiable characters of a true philosopher, that of being content with his fortune in his situation. But the most brilliant part of his character is that of his mathematical genius as an inventor, which was of the first order; as will appear by the following list of his inventions and discoveries. Among many others may be reckoned, his Reflecting Telescope;—Burning Concave Mirror;—Quadrature of the Circle and Hyperbola, by an infinite converging series;—his method for the Transformation of Curves;—a Geometrical Demonstration of lord Brouncker's series for Squaring the Hyperbola;—his Demonstration that the Meridian Line is analogous to a scale of Logarithmic Tangents of the Half Complements of the Latitude;—he also invented and demonstrated geometrically, by help of the hyperbola, a very simple converging series for making the logarithms;—he sent to Mr. Collins the solution of the famous Keplerian problem by an infinite series;—he discovered a method of drawing Tangents to Curves geometrically, without any previous calculations;—a rule for the Direct and Inverse method of Tangents, which stands upon the same principle (of exhaustions) with that of fluxions, and differs not much from it in the manner of application; a Series for the length of the Arc of a Circle from the Tangent, and vice versa; as also for the Secant and Logarithmic Tangent and Secant, and vice versa;—these, with others, for measuring the length of the elliptic and hyperbolic curves, were sent to Mr. Collins, in return for some received from him of Newton's, in which he followed the elegant example of this author, in delivering his series in simple terms, independent of each other. These and other writings of our author are mostly contained in the following works, viz,

1. Optica Promota; 4to, London 1663.
2. Vera Circuli et Hyperbolæ Quadratura; 4to, Padua 1667 and 1668.
3. Geometriae Pars Universalis; 4to, Padua 1668.
4. Exercitationes Geometricæ; 4to, London 1668.
5. The Great and New Art of weighing Vanity, &c. 8vo, Glasgow 1672.

The rest of his inventions make the subject of several letters and papers, printed either in the Philos. Trans. vol. 3; the Commerc. Epistol. Joh. Collins et Alliorum, 8vo, 1715; in the Appendix to the English edition of Dr. David Gregory's Elements of Optics, 8vo, 1735, by Dr.

Desaguliers; and some series in the Exercitatio Geometrica of the same author, 4to, 1684, Edinburgh; as well as in his little piece on practical geometry.—In different parts of the foregoing works, of James Gregory, are found several ingenious thoughts and inventions, that have sometimes been attributed to later periods and authors. Thus, at the end of the Optica Promota, is a collection of curious astronomical problems, conceived and resolved in a very masterly manner; in a scholium at the end of one of which (pa. 130), is remarked the use to be made of the transits of Venus and Mercury, in determining the sun's parallax; an idea which, I think, has usually been ascribed to Dr. Halley.

GREGORY (DR. DAVID), Savilian professor of astronomy at Oxford, was nephew of the above-mentioned Mr. James Gregory, being the eldest son of his brother Mr. David Gregory of Kinardie, a gentleman who had the singular fortune to see three of his sons professors of mathematics, at the same time, in three of the British universities, viz, our author David at Oxford, the second son James at Edinburgh, and the third son Charles at St. Andrews. Our author David, the eldest son, was born at Aberdeen in 1661, where he received the early parts of his education, but completed his studies at Edinburgh; and, being possessed of the mathematical papers of his uncle, soon distinguished himself likewise as the heir of his genius. In the 23d year of his age, he was elected professor of mathematics in the university of Edinburgh; and, in the same year, he published Exercitatio Geometrica de Dimensione Figurarum, sive Specimen Methodi generalis Dimendi quasvis Figuras, Edinb. 1684, 4to. He very soon perceived the excellence of the Newtonian philosophy; and had the merit of being the first who introduced it into the schools, by his public lectures at Edinburgh. “He had (says Mr. Whiston, in the Memoirs of his own Life, i. 32) already caused several of his scholars to keep acts, as we call them, on several branches of the Newtonian philosophy: while we at Cambridge, poor wretches, were ignominiously studying the fictitious hypothesis of the Cartesians.”

On the report of Dr. Bernard's intention of resigning the Savilian professorship of astronomy at Oxford, our author went to London in 1691; and being patronised by Newton, and warmly befriended by Mr. Flamsteed the astronomer-royal, he obtained the vacant professorship, for which Dr. Halley was also a competitor. This rivalship, however, instead of animosity, laid the foundation of friendship between these eminent men; and Halley soon after became the colleague of Gregory, by obtaining the professorship of geometry in the same university. Our author had not long remained in London after his arrival, before he was elected a fellow of the Royal Society; and, previously to his election into the Savilian professorship, had the degree of doctor of physic conferred on him by the university of Oxford.

In 1693, he published in the Philos. Trans. a resolution of the Florentine problem De Testudine veliformi quadrabilis; and he continued to communicate to the public, from time to time, many ingenious mathematical papers through the same channel.

In 1695, he printed at Oxford, Catoptricæ et Dioptricæ Sphaericæ Elementa; a work which, we are informed in the preface, contains the substance of some of his public lectures read at Edinburgh, eleven years before. This valuable treatise was republished in English, first with addi-

tions by Dr. William Brown, with the recommendation of Mr. Jones and Dr. Desaguliers; and afterwards by the latter of these gentlemen, with an appendix containing an account of the Gregorian and Newtonian telescopes, together with Mr. Hadley's tables for the construction of both those instruments. It may not be unworthy of remark, that, in the conclusion of this treatise, there is an observation which shows, that the construction of achromatic telescopes, which Mr. Dollond has carried to such great perfection, had occurred to the mind of David Gregory, from reflecting on the admirable contrivance of nature in combining the different humours of the eye. The passage is as follows: "Perhaps it would be of service to make the object-lens of a different medium, as we see done in the fabric of the eye; where the crystalline humour (whose power of refracting the rays of light differs very little from that of glass) is by nature, who never does any thing in vain, joined with the aqueous and vitreous humours (not differing from water as to their power of refraction), in order that the image may be painted as distinct as possible on the bottom of the eye."

In 1702 our author published at Oxford, in folio, *Astronomiae Physicae et Geometricae Elementa*; a work which is accounted his master-piece. It is founded on the Newtonian doctrines, and was esteemed by Newton himself as a most excellent explanation and defence of his philosophy. In the following year he gave to the world an edition, in folio, of the works of Euclid, in Greek and Latin; being done in prosecution of a design begun by his predecessor Dr. Bernard, of printing the works of all the ancient mathematicians. In this work, which contains all the treatises that have been attributed to Euclid, Dr. Gregory has been careful to point out such as he found reason, from internal evidence, to believe to be the productions of some inferior geometer. In prosecution of the same plan, our author engaged soon after, with his colleague Dr. Halley, in the publication of the *Conics of Apollonius*; but he had proceeded only a little way in this undertaking, when he died at Maidenhead in Berkshire, in 1710, being the 49th year of his age only.

Besides those works published in our author's life-time, as mentioned above, he had several papers inserted in the *Philos. Trans.* vol. 18, 19, 21, 24, and 25, particularly a paper on the catenarian curve, first considered by our author. He left also in manuscript, *A Short Treatise of the Nature and Arithmetic of Logarithms*, which is printed at the end of Keill's translation of Commandine's Euclid; and a *Treatise of Practical Geometry*, which was afterwards translated, and published in 1745, by Mr. Maclaurin.

Dr. David Gregory married, in 1695, Elizabeth, the daughter of Mr. Oliphant of Langtown in Scotland. By this lady he had four sons, of whom, the eldest, David, was appointed regius professor of modern history at Oxford by King George the 1st, and died at an advanced age in 1767, after enjoying for many years the dignity of dean of Christchurch in that university.

When David Gregory quitted Edinburgh, he was succeeded in the professorship at that university, by his brother James, likewise an eminent mathematician; who held that office for 33 years, and, retiring in 1725, was succeeded by the celebrated Maclaurin. A daughter of this professor James Gregory, a young lady of great beauty and accomplishments, was the victim of an unfortunate attachment, that furnished the subject of Mallet's well-known ballad of William and Margaret.

Another brother, Charles, was created professor of mathematics at St. Andrews by Queen Anne, in 1707. This office he held with reputation and ability for 32 years; and, resigning in 1739, was succeeded by his son, who eminently inherited the talents of his family, and died in 1763. *Some further Particulars of the Family of the Gregories and Andersons, communicated by Dr. Thomas Reid, Professor of Moral Philosophy in the University of Glasgow, a Nephew of the late Dr. David Gregory Savilian Professor at Oxford.*

Some account of the family of the Gregories at Aberdeen, is given in the Life of the late Dr. John Gregory prefixed to his works, printed at Edinburgh 1788, in four small 8vo volumes.

Who was the author of that Life, or whence he obtained his information, I do not know. I have heard it ascribed to Mr. Tytler the younger, whose father was appointed one of the guardians of Dr. John Gregory's children. Some addition to what is contained in it, and a few remarks upon it, is all I can furnish on this subject.

Page 3. I know nothing of the education of David Anderson of Finzaugh. He seems to have been a self-taught engineer. Every public work which surpassed the skill of common artists, was committed to the management of David. Such a reputation he acquired by his success in works of this kind, that with the vulgar he got the by-name of Davie do a' thing, that is, in the Scottish dialect, David who could do every thing. By this appellation he is better known than by his proper name. He raised the great bells into the steeple of the principal church: he cut a passage for ships of burden through a ridge of rock under water, which crossed the entrance into the harbour of Aberdeen. In a long picture gallery at Cullen House, the seat of the earl of Findlater, the wooden ceiling is painted with several of the fables of Ovid's Metamorphoses. The colours are still bright, and the representation lively. The present earl's grandfather told me that this painting was the work of David Anderson my ancestor, whom he acknowledged as a friend and relation of his family.

Such works, while they gave reputation to David, suited ill with his proper business, which was that of a merchant in Aberdeen. In that he succeeded ill; and having given up mercantile business, from a small remainder of his fortune began a trade of making malt; and after instructing his wife in the management of the same, left it to her care, and went into England to try his fortune as an engineer; an employment which in his own country he had practised gratuitously. Having in that way realised a fortune which satisfied him, he returned to Aberdeen, where his wife had also made money by her malting business.

After making such provision for their children as they thought reasonable, they agreed that the longest liver of the two should enjoy the remainder, and at death should bequeath it to certain purposes in the management of the magistrates of Aberdeen.

The wife happened to be the survivor, and fulfilled what had been concerted with her husband. Her legacies, well known in Aberdeen, are called after her name Jane Guild's Mortifications, a mortification in Scots law signifying a bequeathment for some charitable purpose. They consist of sums for different purposes: for orphans, for the education of boys and girls, for unmarried gentlewomen, and for widows; and they still continue to be useful to many in indigent circumstances. She was the daughter of Dr. Guild, a minister of Aberdeen. Besides her money, she

bequeathed a piece of tapestry, wrought by her own hand, and representing the history of queen Esther, from a drawing made by her husband. The tapestry continues to ornament the wall of the principal church.

In the same page it is said that Alexander Anderson, professor of mathematics at Paris, was the cousin-german of David above-mentioned. I know not the writer's authority for this: I have always understood that they were brothers; but for this I have only family tradition.

Page 4. It is here related that James Gregory was instructed in the Elements of Euclid by his mother, the daughter of David Anderson. The account I have heard differs from this. It is, that his brother David, being ten or eleven years older, had the direction of his education after their father's death, and, when James had finished his course of philosophy, was at a loss to what literary profession he should direct him. After some unsuccessful trials, he put Euclid's Elements into his hand, and finding that he applied to Euclid with great avidity and success, he encouraged and assisted him in his mathematical studies. This tradition agrees with what James Gregory says in the preface to his *Optica Promota*; where after mentioning his advance to the 26th proposition, he adds, *Ubi diu hæsi omne sp[iritu]e progreendi orbatus, sed continuis hortatibus et auxiliis fratris mei Davidis Gregorii, in Mathematicis non parum versati (cui si quid in illice Scientiis praestitero, me illud debere non incidas ibo) animatus, tandem incidi &c.* Whether David had been instructed in mathematics by his mother, or had any living instructor, I know not.

Page 5, 6. In these two pages I think the merit of Gregory compared with that of Newton in the invention of the catoptric telescope, is put in a light more unfavourable to Newton than is just. Gregory, believing that the imperfection of the dioptric telescope arose solely from the spherical figure of the glasses, invented his telescope to remedy that imperfection. Being less conversant in the practice of mechanics, he did not attempt to make any model. The specula of his telescope required a degree of polish and a figure which the best opticians of that age were unable to execute. Newton demonstrated that the imperfection of the dioptric telescope arose chiefly from the different refrangibility of the rays of light; he demonstrated also that the catoptric telescope required a degree of polish far beyond what was necessary for the dioptric. He made a model of his telescope; and finding that the best polish which the opticians could give, was insufficient, he improved the polish with his own hand, so as to make it answer the intended purpose, and has described most accurately the manner in which he did this. And, had he not given this example of the practicability of making a reflecting telescope, it is probable that it would have passed as an impracticable idea to this day.

Page 11. To what is said of this James Gregory might have been added, that he was led by analogy to the true law of Refraction, not knowing that it was discovered by Descartes before (see Preface to *Optica Promota*); and that in 1670 having received, in a letter from Collins, a series for the area of the zone of a circle, and as Newton had invented an universal method by which he could square all curves geometrical and mechanical by infinite series of that kind; Gregory after much thought discovered this universal method, or an equivalent one. Of this he perfectly satisfied Newton and the other mathematicians of that time, by a letter to Collins in Feb. 1671. He was strongly solicited by his brother David to publish his Uni-

versal Method of Series without delay, but he excused himself on a point of honour; that as Newton was the first inventor, and as he had been led to it by an account of Newton's having such a method, he thought himself bound to wait till Newton should publish his method. I have seen the letters that passed between the brothers on this subject.

With regard to the controversy between James Gregory and Huygens, I take the subject of that controversy to have been, not whether J. Gregory's quadrature of the circle by a converging series was just, but whether he had demonstrated, as in one of his propositions he pretended to do, That it is impossible to express perfectly the Area of a Circle in any known algebraical form, besides that of an infinite converging series. Huygens excepted to the demonstration of this proposition, and Gregory defended it; neither of them convinced his antagonist, nor do I know that Leibnitz improved on what Gregory had done.

Page 12. D. Gregory of Kinardie deserved a more particular account than is here given. It is true that he served an apprenticeship to a mercantile house in Holland, but he followed that profession no longer than he was under authority, having a stronger passion for knowledge than for money. He returned to his own country in 1655, being about 28 years of age, and from that time led the life of a philosopher. Having succeeded to the estate of Kinardie by the death of an elder brother, he lived there to the end of that century. There all his children were born, of whom he had thirty-two by two wives. Kinardie is above 40 English miles north from Aberdeen, and a few miles from Bamf, upon the river Diveron. He was a jest among the neighbouring gentlemen for his ignorance of what was doing about his own farm, but an oracle in matters of learning and philosophy, and particularly in medicine, which he had studied for his amusement, and begun to practise among his poor neighbours. He acquired such a reputation in that science, that he was afterwards employed by the nobility and gentlemen of that county, but took no fees. His hours of study were singular. Being much occupied through the day with those who applied to him as a physician, he went early to bed, rose about two or three in the morning, and, after studying some hours, went to bed again and slept an hour or two before breakfast.

He was the first man in that country who had a barometer; and by some old letters which I have seen, it appeared, that he had corresponded with some philosophers on the continent about the changes in the barometer and in the weather, particularly with Mariotte the French philosopher. He was once in danger of being prosecuted as a conjurer by the Presbytery on account of his barometer. A deputation of that body having waited upon him to enquire into the ground of certain reports that had come to their ears, he satisfied them so far as to prevent the prosecution of a man known to be so extensively useful by his knowledge of medicine.—About the beginning of the last century he removed with his family to Aberdeen, and in the time of Queen Anne's war employed his thoughts upon an improvement in artillery, in order to make the shot of great guns more destructive to the enemy, and executed a model of the engine he had conceived. I have conversed with a clock-maker in Aberdeen who was employed in making this model; but having made many different pieces by direction, without knowing their intention, or how they were to be put together, he could give no account

of the whole. After making some experiments with this model, which satisfied him, the old gentleman was so sanguine in the hope of being useful to the allies in the war against France, that he set about preparing a field equipage with a view to make a campaign in Flanders, and in the mean time sent his model to his son the Savilian professor, that he might have his and Sir Isaac Newton's opinion of it. His son showed it to Newton, without letting him know that his own father was the inventor. Sir Isaac was much displeased with it, saying, that if it tended as much to the preservation of mankind as to their destruction, the inventor would have deserved a great reward; but as it was contrived solely for destruction, and would soon be known by the enemy, he rather deserved to be punished; and urged the professor very strongly to destroy it, and if possible to suppress the invention. It is probable the professor followed this advice; for at his death, which happened soon after, the model was not to be found.

When the rebellion broke out in 1715, the old gentleman went a second time to Holland, and returned when it was over to Aberdeen, where he died about 1720, aged 93. He left an historical manuscript of the transactions of his own time and country, which my father told me he had read. I was well acquainted with two of this gentleman's sons, and with several of his daughters, besides my own mother. The facts abovementioned are taken from what I have occasionally heard from them, and from other persons of his acquaintance.

Page 14. In confirmation of what is said in this page, that the two brothers David and James were the first who taught the Newtonian philosophy in the Scotch Universities; I have by me a Thesis, printed at Edinburgh in 1690, by James Gregory, who was at that time a professor of philosophy at St. Andrews, and succeeded his brother David in the profession of mathematics at Edinburgh. In this Thesis, after a dedication to viscount Tarbet, follow the names of twenty-one of his scholars who were candidates for the degree of A. M., then 25 positions or Theses. The first three relate to logic, and the abuse of it in the Aristotelian and Cartesian philosophy. He defines logic to be the art of making a proper use of things granted, in order to find what is sought, and therefore admits only two Categories in logic, viz. *Datus* and *Quæsita*. The remaining 22 positions are a compend of Newton's Principia. This Thesis, as was the custom at that time in the Scotch universities, was to be defended in a public disputation, by the candidates, previous to their taking their degree.

The famous Dr. Pitcairn was a fellow-student and intimate companion of these two Gregories, and during the vacation of the college was accustomed to go home with them to Kinardie, to their father's house.

David Gregory was appointed a preceptor to the duke of Gloucester, Queen Anne's son; but his entering on that office was prevented by the death of that prince in the 11th year of his age.

Page 19. D. Gregory's Euclid is said to have been written in prosecution of a design of his predecessor Dr. Bernard, of printing the works of all the ancient mathematicians. This design ought to have been ascribed to Saville, who left in charge to the two professors of his foundation, to print the mathematical works of the ancients, and I think left also a fund for defraying the expense. Wallis did something in consequence of this charge; Gregory and Halley performed a great deal; but I think nothing has been done in this design by the Savilian professors since their time.

Page 20. Besides what is above mentioned, Dr. Gregory left in manuscript a Commentary on Newton's Principia, which Newton valued, and kept by him for many years after the author's death. It is probable that in what relates to astronomy, this commentary may coincide in a great measure with the author's astronomy, which indeed is an excellent commentary upon that part of the Principia.

Page 24. This David Gregory published in Latin, a very good compendium of arithmetic and algebra, with the title *Arithmetica et Algebra Compendium, in Usum Juventutis Academice*, Edinb. 1736. He had a design of publishing his uncle's Commentary on the Principia, with extracts from the papers left by James Gregory his grandfather; but the expense being too great for his fortune, and he too gentle a solicitor of the assistance of others, the design was dropped. His son David, yet alive, was master of an East-India ship.

Page 40. To the projectors of the society at Aberdeen, ought to have been added John Stewart, professor of mathematics in the Marischal college at Aberdeen. He published an explanation of two treatises of Sir Isaac Newton, viz., his Quadrature of Curves, and his Analysis by Equations of an infinite number of terms. He was an intimate friend of Dr. Reid's.

Another of the first members of that society was Dr. David Skene, who, besides his eminence in the practice of medicine, had applied much to all parts of natural history, particularly to botany, and was a correspondent of the celebrated Linnæus.

Dr. John Gregory and Dr. David Skene were the first who attempted a college of medicine at Aberdeen. The first gave lectures to his pupils in the theory and practice of medicine, and in chemistry; the last, in anatomy, materia medica, and midwifery, in order to prepare them for attending the medical college at Edinburgh. T. R.
The following additional lines by Mr. James Millar, Professor of Mathematics, Glasgow.

Another instance of the prevalence of mathematical genius in the family of Gregory or Anderson, whether produced by an original and inexplicable determination of the mind, or communicated by the force of example, and the consciousness of an intimate connexion with a reputation already acquired in a particular line, is the celebrated Dr. Reid, professor of moral philosophy in the university of Glasgow; a nephew, by his mother, of the late Dr. David Gregory, Savilian professor at Oxford.

This gentleman, well known to the public by his moral and metaphysical writings, and remarkable for that liberality, and that ardent spirit of inquiry, which neither overlooks nor undervalues any branch of science, is peculiarly distinguished by his abilities and proficiency in mathematical learning. The objects of literary pursuit are often directed by accidental occurrences. An apprehension of the bad consequences which might result from the philosophy of the late Mr. Hume, induced Dr. Reid to combat the doctrines of that eminent author; and produced a work, which has excited universal attention, and has given a new turn to speculations on that subject. But it is well known to Dr. Reid's literary acquaintance, that these exertions have not diminished the original bent of his genius, nor blunted the edge of his inclination for mathematical researches; which, at a very advanced age, he still continues to prosecute with a youthful attachment, and with unremitting assiduity.

It may further be observed, of the extraordinary family above mentioned, that Dr. James Gregory, the present

learned professor of physic and medicine in the university of Edinburgh, is the son of the late Dr. John Gregory, upon the memoirs of whose life the above remarks have been written by Dr. Reid. The said James has lately published a most ingenious work, entitled, Philosophical and Literary Essays, in 2 volumes 8vo, Edinb. 1792; and he appears to be another worthy inheritan; of the singular genius of his family.

GREGORY (ST. VINCENT), a very respectable Flemish geometrician, was born at Bruges in 1584, and became a Jesuit at Romeat 20 years of age. He studied mathematics under the learned Jesuit Clavius. He afterwards became a reputable professor of those sciences himself, and his instructions were solicited by several princes: he was called to Prague by the emperor Ferdinand the 2d; and Philip the 4th, king of Spain, was desirous of having him to teach mathematics to his son the young prince John of Asturia. He was not less estimable for his virtues, than his skill in the sciences. His well-meant endeavours were very commendable, when his holy zeal, though for a false religion, led him to follow the army in Flanders one campaign, to confess the wounded and dying soldiers, in which he received several wounds himself. He died of an apoplexy at Ghent, in 1607, at 83 years of age.

As a writer, Gregory St. Vincent was very diffuse and voluminous, but he was an excellent geometrician. He published, in Latin, three mathematical works, the principal of which was his Opus Geometricum Quadratura Circuli, et Sectionum Coni, Antwerp. 1647, 2 vol. folio. Though he has not demonstrated, in this work, the quadrature of the circle, as he pretends to have done, the book nevertheless contains a great number of truths and important discoveries; one of which is this, viz, that if one asymptote of an hyperbola be divided into parts in geometrical progression, and from the points of division ordinates be drawn parallel to the other asymptote, they will divide the space between the asymptote and curve into equal portions; whence it was shown by Mersenne, that, by taking the continual sums of those parts, there would be obtained areas in arithmetical progression, adapted to abscissæ in geometrical progression, and which therefore were analogous to a system of logarithms.

GRENADE, or GRENADO. See GRANADE.

GRIMALDI (AUTH. FRANC. MARIA), was a learned Italian Jesuit, and one of those philosophers of the 17th century to whom the sciences of optics and astronomy owe great obligations; sciences which he cultivated in compact with his compatriot Riccioli, by diligent experiments and observations. He noticed the spots in the sun, and gave to those in the moon names which are still in use, denominating them after the most eminent astronomers and philosophers. He made numerous experiments on optics, and some discoveries, which were afterwards confirmed and much farther extended by the brilliant discoveries of Newton. Those were chiefly contained in his work, Physico Mathesis de Lumine, Coloribus, et Iride, &c: Bononiae, 1665, in 4to; a work which exhibits a great quantity of curious experiments and remarks on light and colours; a particular account of which may be seen in my Abridg. of the Philos. Trans. vol. 1, pa. 675. This indeed was Grimaldi's chief merit: for his philosophy was but too much after the manner of his country, which, though it has given to the world a Galileo, a Torricelli, &c, was not the first to shake off the yoke of Aristotle. To his honour however it must be acknowledged, that had he lived in another country, and under other authority than that of

his Society, he would have boldly opposed the dogmas of the ancient philosophy.—Grimaldi was cut off at a very early period, in 1663, being only 44 years of age.

GRINDING Telescope Glasses, &c.

GROIN, with builders, is the angle made by the intersection of two arches. It is of two kinds, regular and irregular; viz, regular when both the arches have the same diameter, but an irregular groin when one arch is a semicircle and the other a semielipsis. Groins are chiefly used in forming arched roofs, where one hollow arched vault intersects with another; as in the roofs of most churches, and in some cellars in large houses.

GRUS, the *Crane*, one of the new constellations, in the southern hemisphere; containing, according to Mr. Sharp's catalogue, 13 stars.

GRUS is also one of the Arabian constellations, and answers to our Ophiucus, to which they changed this constellation, their religion prohibiting them from drawing any human figures.

GRY, a measure containing $\frac{1}{20}$ of a line. A line is $\frac{1}{10}$ of a digit, and a digit is $\frac{1}{5}$ of a foot, and a philosophical foot $\frac{3}{5}$ of a pendulum, whose vibrations, in the latitude of 45 degrees, are each performed in one second of time, or $\frac{1}{60}$ of a minute.

GUARDS, a name that has been sometimes applied to the two stars nearest the north pole; being in the hind part of the chariot, at the tail of Ursa Minor, or little bear; one of them being also called the pole-star.

GUERICKE (OTTO OR ORNO), counsellor to the elector of Brandenburg and burgomaster of Magdebourg, was born in 1602, and died in 1686 at Hambourg. He was one of the greatest philosophers of his time. It was Guericke that invented the air-pump; also the two brass hemispheres, which being applied to each other, and the air exhausted, it is said several horses were not able to draw them asunder; and the marmouset or virunculus of glass which descended in a tube against rain, and rose again on the return of serene weather. This last machine fell into disuse on the invention of the barometer, especially after Huygens and Amontons gave theirs to the world. Guericke made use of his marmouset to foretell storms; whence he was looked upon as a sorcerer by the people; so that the thunder having one day fallen upon his house, and shivered to pieces several machines which he had employed in his experiments, they failed not to construe the event into a punishment from heaven that was angry with him.—Guericke was author of several works in natural philosophy, the principal of which was his Experimenta Magdeburgica, in folio, which contains his experiments on a vacuum.

GUERITE, in Fortification, a sentry-box; being a small tower of wood, or stone, usually placed on the point of a bastion, or on the angles of the shoulder, to hold a sentinel, who is to take care of the ditch, and watch against a surprise.

GUEULE, in Architecture. See GULA.

GUGLIELMINI (DOMINIC), an eminent Italian mathematician and civil engineer, was born at Bologna in 1655. His favourite studies were the mathematics and medicine, of which latter faculty he was admitted to the degree of doctor by the university of Bologna, in 1678. On the appearance of the remarkable comet in the years 1680 and 1681, he published a treatise De Cometarum Natura et Ortu, &c, 1681, in which he proposed a new system on the subject, which did not, however, meet with the approbation of the scientific world. But his next

astronomical treatise, containing remarks on the solar eclipse of July 12, 1684, reflected greater credit on his knowledge and accuracy of observation. Soon afterwards, the senate of Bologna appointed him principal professor of mathematics in their university, and, in the year 1686, intendant-general of the rivers of the Bolognese. In consequence of his attention to the duties of this office, in the year 1690 he published the first part, and in the following year the 2d part, of his hydrostatical treatise, entitled *Aquarum Fluuentium Mensura, Novo Methodo Inquisita*. Some of the observations in this work were attacked by M. Papin, who also entered into a contest with the author on the subject of syphons. Their difference in opinion gave rise to two letters by Guglielmini, which were printed under the title of *Epistola Duae Hydrostaticae*.

Sig. G. was engaged in settling the differences which arose between the cities of Bologna and Ferrara, respecting the management of the embankment and sluices in their contiguous districts; and received, in reward of his services from his native city, the appointment to a new office in the university, which was that of professor of hydrometry. In the year 1695 he assisted M. Cassini in repairing the meridian line which he had drawn 40 years before in the church of St. Petronius, at Bologna; on which occasion our author published a memoir, descriptive of the method of laying it down, and establishing its claims to correctness and accuracy. In the year 1697 he published his grand physico-mathematical treatise on the nature of rivers, entitled *Della Natura de Fiume*, which raised his reputation to the highest pitch for hydraulic science. This reputation procured him the honour of being employed by the dukes of Mantua, of Parma, and Modena, the grand-duke of Tuscany, Pope Clement the 11th, the republics of Venice and Lucca, &c, in the invention and construction of the proper hydraulic works in their respective territories.

In the year 1698, our author was induced, by the republic of Venice, to accept of the mathematical chair in the university of Padua; and the senate of Bologna decreed that he should still retain the title of professor in their university, and the emoluments annexed to it. In 1702 he exchanged his mathematical chair at Padua, for the more lucrative one of medicine; after which he published different tracts on chemical and medical subjects. He died at Padua in 1710, in the 55th year of his age. He had been admitted a member of the Academy of Sciences at Paris in 1696, and was also associate, or correspondent member of the academies of Berlin and Vienna, and of the Royal Society at London.—The whole of his works were printed in a collective form at Geneva, in 1719, in 2 vols. 4to; but the best edition of his treatise on the nature of rivers has been published at Bologna in 1756, with the notes of Manfredi.

GUINEA, a gold coin struck in England.—The value or rate of the guinea has varied. It was at first equal to 20 shillings; but by the scarcity of gold it was afterwards advanced to 21s. 6d.; and then reduced to 21s. For some years past (1812) it has disappeared from common circulation, and clandestinely sold at 27s. or 28s.

The pound weight troy of gold is cut into 44 parts and a half, and each part makes a guinea; which is therefore equal to $\frac{5}{9}$ lb., or $\frac{2}{9}\frac{1}{2}$ oz, or 5 dwts. $9\frac{1}{2}$ gr.

This coin took its name, Guinea, from the circumstance of the gold of which it was first struck being brought from that part of Africa called Guinea, for which reason also it bore the impression of an elephant.

GULA, GUEULE, or GOLA, in Architecture, a wavy member whose contour resembles the letter s, commonly called an ogee.

GULBE, in Architecture, the same as *Gorge*.

GULDIN (FATHER), was born at St. Gall in 1577, entered into the society of the Jesuits in 1597, after abjuring the protestant religion, and died in 1643. Having been sent to Rome to improve his talents, he became professor of philosophy and mathematics in that city. He also publicly taught the same sciences at Gratz, and at Vienna, where, in 1635, 1640, and 1641, his chief work was printed in a large folio volume, on the Centre of Gravity, or the Centrobaric Method, being a very elaborate geometrical work.

GULF, or GULPH, in Geography, a part of the ocean running up into the land through a narrow passage, or strait, and forming a bay within. As, the Gulf of Venice, or Adriatic Sea; the Gulf of Arabia, or of Persia, which is the Red Sea; the Gulf of Constantinople, or the Black Sea; the Gulf of Mexico, &c.

GUN, a fire-arm, or weapon of offence, which forcibly discharges a ball or other matter through a cylindrical tube, by means of inflamed gunpowder.

The term gun now includes most of the species of firearms; mortars and pistols being almost the only ones excepted from this denomination. They are divided into great and small guns: the former including all that are usually called cannon, ordnance, or artillery; and the latter musquets, firelocks, carbines, musketoons, blunderbusses, fowling-pieces, &c.

It is not certainly known at what time these weapons were first invented. And though the introduction of guns into the western part of the world is but of modern date, comparatively speaking, yet it is certain that in some parts of Asia they had been used for many ages before, though in a very rude and imperfect manner. Philostratus speaks of a city near the river Hyphasis in the Indies, which was said to be impregnable, and that its inhabitants were relations of the gods, because they threw thunder and lightning upon their enemies; and other Greek authors, as also Quintus Curtius, mention the same thing having happened to Alexander the Great. Hence some have imagined that guns were used by the eastern nations in his time, while others suppose the thunder and lightning alluded to by those authors, were only certain artificial fire-works, or rockets, such as we know are used in the wars by the Indians even in the present day against the Europeans. Be this however as it may, it is asserted by many modern travellers, that guns were used in China as far back as the year of Christ 85, and have continued in use ever since.

The first hint of the invention of guns in Europe, is in the works of Roger Bacon, who flourished in the 13th century. In a treatise written by him about the year 1280, he proposes to apply the violent explosive force of gunpowder to the destruction of armies. And though it is certainly known that the composition of gunpowder is described by Bacon in the said work, yet the invention has usually, though improperly, been ascribed to Bartholdus Schwartz, a German monk, who it is said discovered it only in the year 1320; and the invention is related in the following manner. Schwartz having, for some purpose, pounded nitre, sulphur, and charcoal together, in a mortar, which he afterwards covered imperfectly with a stone, a spark of fire accidentally fell into the mortar, which setting the mixture on fire, the explosion blew the stone

to a considerable distance. Hence it is probable that Schwartz might be taught the simplest method of applying it in war; for it rather seems that Bacon conceived the manner of using it to be by the violent effort of the flame unconfin'd, and which is indeed capable of producing astonishing effects. (See GUNPOWDER.) And the figure and name of mortars, given to a species of old artillery, and their employment, in throwing large stone bullets at an elevation, very much favour this conjecture.

Soon after the time of Schwartz, we find guns commonly employed as instruments of war. Great guns were first used. These were originally made of iron bars soldered together, and fortified with strong iron hoops or rings; several of which are still to be seen in the Tower of London, and in the Arsenal at Woolwich. Others were made of thin sheets of iron rolled together and hooped: and on particular emergencies some have been made of leather, and of lead, with plates of iron or copper. These first pieces were executed in a rude and imperfect manner, like the first essays of most new inventions. Stone balls were thrown out of them, and a small quantity of powder used on account of their weakness. They were of a cylindrical form, without ornaments, and were placed on their carriages by rings.

When, or by whom they were first made, is uncertain. It is known however that the Venetians used cannon at the siege of Claudia Jessa, now called Chioggia, in 1366, which were brought thither by two Germans, with some powder and leaden balls; as also in their wars with the Genoese in 1379. But before that period King Edward the 3d made use of cannon at the battle of Cressy in 1346, and at the siege of Calais in 1347. Cannon were employed by the Turks at the siege of Constantinople, then in possession of the Christians, in 1394, and in that of 1452, which threw a stone ball of 200lb. weight; but they commonly burst at the first two or three firings. Louis the 12th had one cast at Tours, of the same size, which threw a ball from the Bastile to Charenton; one of these extraordinary cannon was taken at the siege of Dieu in 1546, by Don John de Castro, and is now in the castle of St. Julian da Barra, 10 miles from Lisbon: the length of it is 20 feet 7 inches, its diameter at the middle 6 feet 3 inches, and it threw a ball of 100lb. weight. It has neither dolphins, rings, nor button; is of an unusual kind of metal; and it has a large Indostan inscription on it, which says it was cast in 1400.

Formerly, it was customary to dignify cannon with uncommon names. Thus, Lewis the 12th, in 1503, had 12 brass cannon cast, of an extraordinary size, called after the names of the 12 peers of France. The Spanish and Portuguese called them after their saints. The Emperor Charles the 5th, when he marched against Tunis, founded the 12 Apostles. At Milan there is a 70-pounder, called the Pimontelle; and one at Bois-le-duc, called the Devil. A 60-pounder at Dover-castle, called Queen Elizabeth's pocket-pistol. An 80-pounder in the Tower of London, brought thence from Edinburgh-castle, called Mounts-meg. An 80-pounder in the royal arsenal at Berlin, called the Thunderer. An 80-pounder at Malaga, called the Terrible. Two curious 60-pounders in the arsenal at Bremen, called the Messenger of bad news. And lastly an uncommon 70-pounder in the castle of St. Angelo at Rome, made of the nails that fastened the copper-plates which covered the ancient Pantheon, with this inscription on it, Ex clavis trabalibus porticus Agrippae.

In the beginning of the 15th century these uncommon names were generally abolished, and the following more universal ones adopted in their stead, viz,

Names.	Wt. of ball, Pounds.	Wt. of piece in cws. about Cwt.
Cannou royal, or carthoun	48	- . 90
Bastard cannon, or $\frac{3}{4}$ carthoun	36	- . 79
Demi-carthoun	-	24 - . 60
Whole culverins	-	18 - . 50
Demi-culverins	-	9 - . 30
Falcon	-	6 - . 25
Sacker { largest size	-	8 - . 18
ordinary	-	6 - . 15
{ lowest sort	-	5 - . 13
Basilisk	-	48 - . 85
Serpentine	-	4 - . 8
Aspic	-	2 - . 7
Dragon	-	6 - . 12
Syren	-	60 - . 81
Falconet	-	3, 2, and 1 - . 15,10,5
Rabinet	-	1 - .
Moyens	-	10 or 12 oz.

These curious names, of beasts and birds of prey, were adopted on account of their swiftness in motion, or of their cruelty; as the falconet, falcon, sacker, and culverin, &c, for their swiftness in flying; the basilisk, serpentine, aspic, dragon, syren, &c, for their cruelty. But, at present, cannon take their names from the weight of their proper ball only. Thus, a piece that discharges a cast-iron ball of 24 pounds, is called a 24-pounder; one that carries a ball of 12 pounds, is called a 12-pounder: and so of the rest, divided into the following kinds, viz,

Ship-guns, consisting in 42, 36, 32, 24, 18, 12, 9, 6, and 3-pounders. Garrison-guns, in 42, 32, 24, 18, 12, 9, and 6 pounders.

Battering-guns, in 24, 18, and 12-pounders.

Field-pieces, in 12, 9, 6, 3, 2, 1½, 1, and $\frac{1}{2}$ -pounders.

Mortars, it is thought, have been at least as ancient as cannon. They were employed in the wars of Italy, to throw balls of red-hot iron, stones, &c, long before the invention of shells. These last, it is supposed, were of German invention, and the use of them in war shown by the following accident; viz, a citizen of Venlo, at a festival celebrated in honour of the duke of Cleves, throwing a number of shells, one of them fell on a house and set it on fire, by which misfortune the greatest part of the town was reduced to ashes. The first account of shells used for military purposes, is in 1435, when Naples was besieged by Charles the 8th. History informs us, with more certainty, that shells were projected from mortars at the siege of Wachtendonk, in Guelderland, in 1588, by the earl of Mansfield; and Cyprian Lucar wrote upon the method of filling and throwing such shells, in his Appendix to the Colloquies of Tartaglia, printed at London in 1588; where also the compounding and throwing of carcasses and various kinds of fire-works is shown.

Mr. Malter, an English engineer, first taught the French the art of throwing shells, which they practised at the siege of Motte in 1634. The method of firing red-hot balls out of mortars was first certainly put in practice at the siege of Stralsund in 1675 by the elector of Brandenburg: though some say in 1653 at the siege of Bremen.

Another species of ordnance has been long in use, by the name of howitzer, which is a kind of medium as to its

length, between the cannon and the mortar, and is a very useful piece, for discharging either shells or large balls, which is done either at point-blanc, or at a small elevation. A new species of ordnance has lately been introduced by the Carron company, and thence called a Carronade, which is only a very short howitzer, and which possesses the advantage of being very light and easy to work. The species of guns before mentioned, are now made chiefly of cast iron; except the howitzer, which is of brass, as well as some cannon and mortars.

Muskets were first used at the siege of Rhege in the year 1521. The Spaniards were the first who armed part of their foot with these weapons. At first they were very heavy, and could not be used without a rest. They had match-locks, and did execution at a great distance. On their march the soldiers carried only the rests and ammunition, having boys to bear their muskets after them. They were very slow in loading, not only by reason of the unwieldiness of their pieces, and because they carried the powder and ball separate, but from the time it took to prepare and adjust the match; so that their fire was not near so brisk as ours is now. Afterwards a lighter match-lock musket came in use: and they carried their ammunition in bandoliers, to which were hung several little cases of wood covered with leather, each containing a charge of powder. The muskets with rests were used as late as the beginning of the civil wars in the time of Charles the 1st. The lighter kind succeeded them, and continued till the beginning of the present century, when they also were disused, and the troops throughout Europe armed with fire-locks. These are usually made of hammered iron. For the dimensions, construction, and practice of every species of gun, &c, see the several articles CANNON, MORTAR, &c. See also GUNNERY.

GUNNERY, the art of charging, directing, and exploding fire-arms, as cannon, mortars, muskets, &c, to the best advantage. Gunnery is sometimes considered as a part of the military art, and sometimes as a part of pyrotechny. To the art of gunnery belongs the knowledge of the force and effect of gunpowder, the dimensions of the pieces, and the proportions of the powder and ball they carry, with the methods of managing, charging, pointing, spiking, &c. Also some parts of gunnery are subject to mathematical consideration, which among mathematicians are called absolutely by the name gunnery, viz, the rules and method of computing the range, elevation, quantity of powder, &c, so as to hit a mark or object proposed, and is more particularly called PROJECTILES; which see.

HISTORY OF GUNNERY.

Long before the invention of gunpowder, and of gunnery, properly so called, the art of artillery, or projectiles, was actually in practice. For, not to mention the use of spears, javelins, or stones thrown with the hand, or of bows and arrows, all which are found among the most barbarous and ignorant people, accounts of the larger machines for throwing stones, darts, &c, are recorded by the most ancient writers. Thus, one of the kings of Judah, 800 years before the Christian era, erected engines of war on the towers and bulwarks of Jerusalem, for shooting arrows and great stones for the defence of that city. 2 Chron. xxvi, 15. Such machines were afterwards known among the Greeks and Romans by the names of Ballista, Catapulta, &c, which produced effects by the action of a spring of a strongly twisted cordage, formed of tough and elastic animal substances, no less terrible than the artillery of the moderns.

Such warlike instruments continued in use down to the 12th and 13th centuries, and the use of bows still longer; nor is it probable that they were totally laid aside till they were superseded by gunpowder and the modern ordnance.

The first application of gunpowder to military affairs, it seems, was made soon after the year 1300, for which the proposal of friar Bacon, about the year 1280, for applying its enormous explosion to the destruction of armies, might give the first hint; and Schwartz, to whom the invention of gunpowder has been erroneously ascribed, on account of the accident abovementioned under the article GUN, might have been the first who actually applied it in this way, that is in Europe; for as to Asia, it is probable that the Chinese and Indians had something of the kind many ages before. Thus, only to mention the prohibition of firearms in the code of Gentoo laws, printed by the East-India Company in 1776, which seems to confirm the suspicion suggested by a passage in Quintus Curtius, that Alexander the Great found some weapons of that kind in India: Cannon in the Shanscrit idiom is called shet-aghnee, or the weapon that kills a hundred men at once.

However, the first pieces of artillery, which were charged with gunpowder and stone bullets of a prodigious size, were of very clumsy and inconvenient structure and weight. Thus, when Mahomet the 2d besieged Constantinople in 1453, he battered the walls with stones of this kind, and with pieces of the calibre of 1200 pounds; which could not be fired more than four times a day. It was however soon discovered that iron bullets, of much less weight than stone ones, would be more efficacious if impelled by greater quantities of stronger powder. This occasioned an alteration in the matter and form of the cannon, which were now cast of brass. These were lighter and more manageable than the former, at the same time that they were stronger in proportion to their bore. This change took place about the close of the 15th century.

By this means came first into use such powder as is now employed over all Europe, by varying the proportion of the materials. But this change of the proportion was not the only improvement it received. The practice of graining it is doubtless of considerable advantage. At first the powder had been always used in the form of fine meal, such as it was reduced to by grinding the materials together. And it is doubtful whether the first graining of powder was intended to increase its strength, or only to render it more convenient for filling into small charges and the loading of small arms, to which alone it was applied for many years, while meal-powder was still used for cannon. But at last the additional strength which the grained powder was found to possess, doubtless from the free passage of the air between the grains, occasioned the meal-powder to be entirely laid aside.

For the last 200 years, the formation of cannon has been very little improved; the best pieces of modern artillery differing little in their proportions from those used in the time of Charles the 5th. Indeed lighter and shorter pieces have been often proposed and tried; but though they have their advantages in particular cases, it is agreed they are not so efficacious for general service. Yet the size of the pieces has been much diminished; the same purposes being now accomplished by smaller pieces than what were formerly thought necessary. Thus the battering cannon now approved, are those that formerly were called demi-cannon, carrying a ball of 24 pounds weight; this weight

having been found fully sufficient. The method also of making a breach, by first cutting off the whole wall as low as possible before its upper part is attempted to be beaten down, seems to be a considerable modern improvement in the practical part of gunnery. But the most considerable improvement in the practice of artillery, is the ricochet firing, or the method of firing with small quantities of powder, and elevating the piece but a little, so that the bullet may just go clear of the parapet of the enemy, and drop into their works: for by this means the ball, coming to the ground at a small angle, and with a small velocity, does not bury itself, but bounds or rolls along a great way, destroying all before it. This method was first practised by M. Vauban at the siege of Aeth, in the year 1692. A practice of this kind was successfully used by the king of Prussia at the battle of Rosbach in 1757. He had several six-inch mortars, made with trunnions, and mounted on travelling carriages, which were fired obliquely on the enemy's lines, and among their horse. These being charged with only 8 ounces of powder, and elevated at one degree and a quarter, did great execution: for the shells rolling along the lines with burning fuses made the stoutest of the enemy to fly with precipitation.

The use of fire-arms was however long known before any theory of projectiles was formed. The Italians were the first people who made any attempts at the theory, which they did about the beginning of the 16th century; and among them it appears the first who wrote professedly on the flight of cannon shot, was Nicholas Tartalia, of Brescia, the same author who had so great a share in the invention of the rules for cubic equations. In 1537 he published, at Venice, his *Nova Scientia*, and in 1546 his *Quesiti et Inventioni diversi*, in both which he treats professedly on these motions, as well as in another work, translated into English with additions by Cyprian Lucar, under the title of *Colloquies concerning the Art of Shooting in great and small Pieces of Artillery*, and published at London in 1588. Tartalia determined, that the greatest range of a shot was when discharged at an elevation of 45° : and he asserted, contrary to the opinion of his contemporaries, that no part of the path described by a ball is a right line; 'though the curvature in the first part of it is so small, that it need not be attended to. He compared it to the surface of the sea; which, though it appears to be a plane, is yet doubtless incurvated round the centre of the earth.' The same author observes, that he invented the gunner's quadrant, for laying a piece of ordnance at any point or degree of elevation; and though he had but little opportunity of acquiring any practical knowledge by experiments, he yet gave shrewd guesses at the event of some-untried methods.

The philosophers of those times also took part in the questions arising on this subject; and many disputes on motion were held, especially in Italy, which continued till the time of Galileo, and probably gave rise to his celebrated Dialogues on Motion. These were not published till the year 1638; and in the interval there were published many theories of the motion of military projectiles, as well as many tables of their comparative ranges; though for the most part very fallacious, and inconsistent with the motions of these bodies.

It is remarkable however that, during these contests, so few of those who were intrusted with the care of artillery, thought it necessary to bring their theories to the test of experiment. Mr. Robins informs us, in the preface to his *New Principles of Gunnery*, that he had met with no more

than four authors who had treated experimentally on this subject. The first of these is Collado, in 1642, who has given the ranges of a falconet, carrying a three-pound shot, to every point of the gunner's quadrant, each point being the 12th part, or $7\frac{1}{2}^\circ$. But from his numbers it is manifest that the piece was not charged with its usual allotment of powder. The result of his trials shows the ranges at the point-blanc, and the several points of elevation, as below.

Collado's Experiments.

Points.	Elevation at Deg.	Range in paces.
0 or	0	268
1	7 $\frac{1}{2}$	594
2	15	794
3	22 $\frac{1}{2}$	954
4	30	1010
5	37 $\frac{1}{2}$	1040
6	45	1053
7	52 $\frac{1}{2}$	between the 3d and 4th
8	60	between the 2d and 3d
9	67 $\frac{1}{2}$	between the 1st and 2d
10	75	between the 0 and 1st
11	82 $\frac{1}{2}$	fell very near the piece.

The next treatise was by Wm. Bourne, in 1643, in his *Art of Shooting in Great Ordinance*. His elevations were not regulated by the points of the gunner's quadrant, but by degrees; and he gives the proportions between the ranges at different elevations and the extent of the point-blanc shot, thus: If the extent of the point-blanc shot be represented by 1, then the proportions of the ranges at several elevations will be as below, viz.

Bourne's Proportion of Ranges.

Elevation.	Range.
0°	-
5	-
10	-
15	-
20	-

and the greatest random $5\frac{1}{2}$;

which greatest random, he says, in a calm day is at 42° elevation; but according to the strength of the wind, and as it favours or opposes the flight of the shot, the elevation may be from 45° to 36° .—He does not inform us with what piece he made his trials; though from his proportions it seems to have been a small one. This however ought to have been mentioned, as the relation between the extent of different ranges varies extremely according to the velocity and density of the bullet.

After him, Eldred and Anderson, both Englishmen also, published treatises on this subject. The former of these was many years gunner of Dover Castle, where most of his experiments were made, the earliest of which are dated in 1611, though his book was not published till 1646, and was entitled *The Gunner's Glass*. His principles were sufficiently simple, and within certain limits very near the truth, though they were not rigorously so. He has given the actual ranges of different pieces of artillery at small elevations, all under 10 degrees. His experiments are numerous, and appear to be made with great care and caution; and he has honestly set down some, which were not reconcilable to his method: on the whole he seems to have taken more pains, and to have had a juster knowledge of his business, than is to be found in most of his practical brethren.

Galileo's Dialogues on Motion were printed in the year 1646. In these he pointed out the general laws observed by nature in the production and composition of motion, and was the first who described the action and effects of gravity on falling bodies: on these principles he determined, that the flight of a cannon-shot, or of any other projectile, would be in the curve of a parabola, unless so far as it should be diverted from that track by the resistance of the air. He also proposed the means of examining the inequalities which arise from thence, and of discovering what sensible effects that resistance would produce in the motion of a bullet at some given distance from the piece.

Notwithstanding these determinations and hints of Galileo, it seems that those who came after him, never imagined that it was necessary to consider how far the operations of gunnery were affected by this resistance. Instead of this, they boldly asserted, without making the experiment, that no great variation could arise from the resistance of the air in the flight of shells or cannon shot. In this persuasion they supported themselves chiefly by considering the extreme rarity of the air, compared with those dense and ponderous bodies; and at last it became an almost generally established maxim, that the flight of these bodies was nearly in the curve of a parabola.

Thus, Robert Anderson, in his Genuine Use and Effects of the Gunne, published in 1674, and again in his book, To hit a Mark, in 1690, relates a great many experiments; but proceeding on the principles of Galileo, he strenuously asserts that the flight of all bullets is in the curve of a parabola; undertaking to answer all objections that could be brought to the contrary. The same thing was also undertaken by Blondel in his Art de jettier les Bombes, published in 1683; where, after long discussion, he concludes, that the variations from the air's resistance are so slight, as not to deserve any notice. The same subject is treated of in the Philos. Trans. No. 216, pa. 68, by Dr. Halley; who also, swayed by the very great disproportion between the density of the air and that of iron or lead, thought it reasonable to believe that the opposition of the air to large metal-shot is scarcely discernible; though in small and light shot he owns that it must be accounted for.

Though this hypothesis went on smoothly in speculation; yet Anderson, who made a great number of trials, found it impossible to support it without some new modification. For though it does not appear that he ever examined the comparative ranges of either cannon or musket-shot when fired with their usual velocities, yet his experiments on the ranges of shells thrown with velocities that were but small, in comparison of those above mentioned, convinced him that their whole track was not parabolical. But instead of making the proper inferences from hence, and concluding that the resistance of the air was of considerable efficacy, he framed a new hypothesis; which was, that the shell or bullet at its first discharge flew to a certain distance in a right line, from the end of which line only it began to describe a parabola: and this right line, which he calls the line of the impulse of the fire, he supposes is the same for all elevations. So that, by assigning proper length to this line of impulse, it was always in his power to reconcile any two shots made at any two different angles; though the same method could not succeed with three shots; nor indeed does he ever inform us of the event of his experiments when three ranges were tried at one time.

But after the publication of Newton's Principia, it might have been expected, that the defects of the theory would be ascribed to their true cause, which is the great resistance of the air to such swift motions; as in that work he particularly considered the subject of such motions, and related the result of experiments, made on slow motions at least; by which it appeared, that in such motions the resistance increases as the square of the velocities, and he even hints a suspicion that it will increase above that law in swifter motions, as is now known to be the case. So far however were those who treated this subject scientifically, from making a proper allowance for the resistance of the atmosphere, that they still neglected it, or rather opposed it, and their theories still differed most egregiously from the truth. Huygens alone seems to have attended to this principle: for in the year 1690 he published a treatise on gravity, in which he gave an account of some experiments tending to prove that the track of all projectiles, moving with very swift motions, was widely different from that of a parabola. The rest of the learned generally acquiesced in the justness and sufficiency of Galileo's doctrine, and accordingly very erroneous calculations concerning the ranges of cannon were given. Nor was any farther notice taken of these errors till the year 1716, when Mr. Ressons, a French officer of artillery, of great merit and experience, gave in a memoir to the Royal Academy, importuning that, "though it was agreed that theory joined with practice did constitute the perfection of every art; yet experience had taught him that theory was of very little service in the use of mortars: that the works of M. Blondel had justly enough described the several parabolic lines, according to the different degrees of the elevation of the piece; but that practice had convinced him there was no theory in the effect of gunpowder; for having endeavoured, with the greatest precision, to point a mortar according to these calculations, he had never been able to establish any solid foundation upon them."—One instance only occurs in which D. Bernoulli applies the doctrine of Newton to the motions of projectiles, in the Com. Acad. Petrop. tom. 2, pa. 338, &c. Besides which nothing farther was done in this science till the time of Mr. Benjamin Robins, who published a treatise in 1742, intitled New Principles of Gunnery, in which he treated particularly, not only of the resistance of the atmosphere, but also of the force of gunpowder, the nature and effects of different guns, and almost every thing else relating to the flight of military projectiles; and indeed he carried the theory of gunnery nearly to its utmost perfection.

The first important consideration which engaged the attention of Mr. Robins, and which is indeed the foundation of all other particulars relating to gunnery, is the explosive force of gunpowder. M. Lahire, in the Hist. of the Acad. of Sciences for the year 1702, supposed that this force may be owing to the increased elasticity of the air contained in, and between the grains, in consequence of the heat and fire produced at the time of the explosion: a cause not adequate to the 200th part of the effect. On the other hand, Mr. Robins determined, by irrefragable experiments, that this force was owing to an elastic fluid, similar to our atmosphere, existing in the powder in an extremely condensed state, which being suddenly disengaged from the powder by the combustion, expanded with an amazing force, and violently impelled the bullet, or whatever may oppose its expansion.

In ascertaining the intensity of this force of exploded gunpowder, Mr. Robins had recourse to several different ways, after the example of Mr. Hawksbee, related in the Philos. Trans. No. 295, and his Physico-Mechan. Exper. pa. 81. One of these is by firing the powder in the air thus: A small quantity of the powder is placed in the upper part of a glass tube, and the lower part of the tube is immersed in water, the water being made to rise so near the top, that only a small portion of air is left in that part where the powder is placed: then in this situation the communication between the upper part of the tube and the external air being closed, the powder is fired by means of a burning glass, or otherwise; the water descends upon the explosion, and stands lower in the tube than before, by a space proportioned to the quantity of powder fired.

Another method was by firing the powder in vacuo, viz., in an exhausted receiver, by dropping the grains of powder upon a hot iron included in the receiver. By this means a permanent elastic fluid was generated from the fired gunpowder, and the quantity of it was always in proportion to the quantity of powder that was used, as was found by the proportional sinking of the mercurial gage annexed to the air pump. The result of these experiments was, that the weight of the elastic air thus generated, was equal to $\frac{2}{3}$ of the compound mass of the gunpowder which yielded it; and that its bulk, when cold and expanded to the rarity of common atmospheric air, was about 240 times the bulk of the powder; and consequently in the same proportion would such fluid at first, if it were cold, exceed the force or elasticity of the atmosphere. But as Mr. Robins found, by another ingenious experiment, that air heated to the extreme degree of the white heat of iron, has its elasticity quadrupled, or is 4 times as strong; he thence inferred that the force of the elastic air generated as above, at the moment of the explosion, is at least 4 times 240, or 960, or in round numbers about 1000 times as strong as the elasticity or pressure of the atmosphere, on the same space.

Having thus determined the force of the gunpowder, or intensity of the agent by which the projectile is to be urged, Mr. Robins next proceeds to determine the effects it will produce, or the velocity with which it will impel a shot of a given weight from a piece of ordnance of given dimensions; which is a problem strictly limited, and perfectly soluble by mathematical rules, and isⁱⁿ general this: Given the first force, and the law of its variation, to determine the velocity with which it will impel a given body in passing through a given space, which is the length of the bore of the gun.

In the solution of this problem, Mr. Robins assumes these two postulates, viz, 1, That the action of the powder on the bullet ceases as soon as the bullet is out of the piece; and 2d, That all the powder of the charge is fired and converted into elastic fluid before the bullet is sensibly moved from its place: assumptions which for good reasons are found to be in many cases very near the truth. It is to be noted also, that the law by which the force of the elastic fluid varies, is this, viz, that its intensity is directly as its density, or reciprocally proportional to the space it occupies, being so much the stronger as the space is less; a principle well known, and common to all elastic fluids. On these principles then Mr. Robins resolves this problem, by means of the 39th prop. of Newton's Principia in a direct way, and the result is equivalent to this theor-

em, when the quantities are expressed by algebraic symbols; viz, the velocity of the ball
 $v = 27130 \sqrt{\left(\frac{12a}{cd} \times \log \frac{b}{a}\right)} = 100 \sqrt{\left(\frac{223ad^2}{w} \times \log \frac{b}{a}\right)}$
 where v is the velocity of the ball,
 a the length of the charge of powder,
 b the whole length of the bore,
 c the spec. grav. of the ball, or wt. of a cubic foot of
 the same matter in ounces,
 d the diameter of the bore,
 w the weight of the ball in ounces.

For Example, Suppose $a = 2\frac{1}{2}$ inc., $b = 45$ inches, $c = 11345$ oz, for a ball of lead, and $d = \frac{3}{4}$ inches; then
 $v = 27130 \sqrt{\left(\frac{7}{2269} \times \log \frac{120}{7}\right)} = 1674$ feet per second, the velocity of the ball.

Or, if the wt. of the bullet be $w = 1\frac{1}{2}$ oz. = $\frac{29}{20}$ oz. Then $v = 100 \sqrt{\left(\frac{1115 \times 189}{29 \times 32} \times \log \frac{120}{7}\right)} = 1674$ feet, as before.

" Having in this proposition," says Mr. Robins, " shown how the velocity, which any bullet acquires from the force of powder, may be computed upon the principles of the theory laid down in the preceding propositions; we shall next show, that the actual velocities, with which bullets of different magnitudes are impelled from different pieces, with different quantities of powder, are really the same with the velocities assigned by these computations; and consequently that this theory of the force of powder, here delivered, does unquestionably ascertain the true action and modification of this enormous power."

" But in order to compare the velocities communicated to bullets by the explosion with the velocities resulting from the theory by computation; it is necessary that the actual velocities with which bullets move, should be capable of being discovered, which yet is impossible to be done, by any methods hitherto made public. The only means hitherto practised by others for that purpose, have been either by observing the time of the flight of the shot through a given space, or by measuring the range of the shot at a given elevation; and thence computing, on the parabolic hypothesis, what velocity would produce this range. The first method labours under this insurmountable difficulty, that the velocities of these bodies are often so swift, and consequently the time observed is so short, that an imperceptible error in that time may occasion an error in the velocity thus found, of 2, 3, 4, 5, or 600 feet in a second. The other method is so fallacious, by reason of the resistance of the air (to which inequality the first is also liable), that the velocities thus assigned may not be perhaps the 10th part of the actual velocities sought."

" To remedy then these inconveniences, I have invented a new method of finding the real velocities of bullets of all kinds; and this to such a degree of exactness (which may be augmented too at pleasure), that in a bullet moving with a velocity of 1700 feet in 1", the error in the estimation of it need never amount to its 500th part; and this without any extraordinary nicety in the construction of the machine."

Mr. Robins then gives an account of the machine by which he measures the velocities of the balls, which machine is simply this, viz, a pendulous block' of wood suspended freely by a horizontal axis, against which block are to be fired the balls whose velocities are to be determined.

" This instrument thus fitted, if the weight of the pendulum be known, and likewise the respective distances of its centre of gravity, and of its centre of oscillation, from its axis of suspension, it will thence be known what motion will be communicated to this pendulum by the percussion of a body of a known weight moving with a known degree of celerity, and striking it in a given point; that is, if the pendulum be supposed at rest before the percussion, it will be known what vibration it ought to make in consequence of such a determined blow; and, on the contrary, if the pendulum, being at rest, is struck by a body of a known weight, and the vibration, which the pendulum makes after the blow, is known, the velocity of the striking body may be hence determined.

" Hence then, if a bullet of a known weight strikes the pendulum, and the vibration, which the pendulum makes in consequence of the stroke, be ascertained; the velocity with which the ball moved, is thence to be known."

Mr. Robins then explains his method of computing velocities from experiments with this machine; which method is rather troublesome and perplexed, as well as the rules of Euler and Antoni, who followed him in these investigations; but a much simpler rule is given in my Tracts, vol. 2, pa. 325, where such experiments are explained at full length, and this rule is expressed by either of the two following formulas,

$$v = 5.6727cg \times \frac{p+b}{bir} \sqrt{o} = 614.58cg \times \frac{p+b}{birn}, \text{ the velocity}$$

city; where v denotes the velocity of the ball when it strikes the pendulum, p the weight of the pendulum, b the weight of the ball, c the chord of the arc described by the vibration to the radius r , g the distance below the axis of motion to the centre of gravity, o the distance to the centre of oscillation, i the distance to the point of impact, and n the number of oscillations the pendulum will perform in one minute, when made to oscillate in small arcs. "The latter of these two theorems is much the easiest, both because it is free of radicals, and because the value of the radical \sqrt{o} , in the former, is to be first computed from the number n , or number of oscillations the pendulum is observed to make.

With such machines Mr. Robins made a great number of experiments, with musket barrels of different lengths, with balls of various weights, and with different charges or quantities of powder. He has set down the results of 61 of these experiments, which nearly agree with the corresponding velocities as computed by his theory of the force of powder, and which therefore establish that theory on a sure foundation.

From these experiments, as well as from the preceding theory, many important conclusions were deduced by Mr. Robins; and indeed by means of these it is obvious that every thing may be determined relative both to the true theory of projectiles, and to the practice of artillery. For, by firing a piece of ordnance, charged in a similar manner, against such a ballistic pendulum from different distances, the velocity lost by passing through such spaces of air will be found, and consequently the resistance of the air, the only circumstance that was wanting to complete the theory of gunnery, or military projectiles; and of this kind I have since made a great number of experiments with cannon balls, and have thereby obtained the whole series of resistances to such a ball when moving with every degree of velocity, from 0 up to 2200 feet per second of time. In the structure of artillery, they may

likewise be of the greatest use: for hence may be determined the best lengths of guns; the proportions of the shot and powder to the several lengths; the thickness of a piece, so as it may be able to confine, without bursting, any given charge of powder; as also the effect of wads, chambers, placing of the vent, ramming the powder, &c. For the many other curious circumstances relating to this subject, and the various other improvements in the theory and practice of gunnery, made by Mr. Robins, consult the first vol. of his Tracts, collected and published by Dr. Wilson, in the year 1761, and republished with many important notes, and observations, by the author of this work, in 1805, where ample information may be obtained.

Soon after the first publication of Robins's New Principles of Gunnery, in 1742, the learned in several other nations, treading in his steps, repeated and farther extended the same subject, sometimes varying and enlarging the machinery; particularly Euler in Germany, D'Antoni in Italy, and Messrs. D'Arcy and Le Roy in France. But most of these, like Mr. Robins, with small fire-arms, such as muskets and fusils.

But in the year 1775, in conjunction with several able officers of the royal artillery, and other ingenious gentlemen, was undertaken a course of experiments with the ballistic pendulum, in which we ventured to extend the machinery to cannon shot of 1, 2, and 3 pounds weight. An account of these experiments was published in the Philos. Trans. for 1778, and for which the Royal Society honoured me with the prize of the gold medal. "These were the only experiments that I know of which had been made with cannon balls for this purpose, though the conclusions to be deduced from such, are of the greatest importance to those parts of natural philosophy which are dependent on the effects of fired gunpowder; nor do I know of any other practical method of ascertaining the initial velocities within any tolerable degree of the truth. The knowledge of this velocity is of the utmost consequence in gunnery: by means of it, together with the law of the resistance of the medium, every thing is determinable relative to that science; for, besides its being an excellent method of trying the strength of different kinds of powder, it gives us the law relative to the different quantities of powder, to the different weights of shot, and to the different lengths and sizes of guns. Besides these, there does not appear to be any thing wanting to answer any inquiry that can be made concerning the flight and ranges of shot, except the effects arising from the resistance of the medium. In these experiments the weights of the pendulums employed were from 300 to near 600 pounds. In that paper is described the method of constructing the machinery, of finding the centres of gravity and oscillation of the pendulum, and of making the experiments, which are all set down in the form of a journal, with all the minute and concomitant circumstances; as also the investigation of the new and easy rule, given above, for computing the velocity of the ball from the experiments. The charges of powder were varied from 2 to 8 ounces, and the shot from 1 to near 3 pounds. And from the whole were clearly deduced these principal inferences, viz.

" 1. First, That gunpowder fires almost instantaneously.—2. That the velocities communicated to balls or shot, of the same weight, by different quantities of powder, are nearly in the subduplicate ratio of those quantities: a small variation, in defect, taking place when the quantities of powder became great.—3. And when shot of dif-

ferent weights are employed, with the same quantity of powder, the velocities communicated to them, are nearly in the reciprocal subduplicate ratio of their weights.—
4. So that, universally, shot which are of different weights, and impelled by the flame of different quantities of powder, acquire velocities which are directly as the square roots of the quantities of powder, and inversely as the square roots of the weights of the shot, nearly.—5. It would therefore be a great improvement in artillery, to make use of shot of a long form, or of heavier matter; for thus the momentum of a shot, when fired with the same weight of powder, would be increased in the ratio of the square root of the weight of the shot.—6. It would also be an improvement to diminish the windage; for so doing, one-third or more of the quantity of powder might be saved.—7. When the improvements mentioned in the last two articles are considered as both taking place, it is evident that about half the quantity of powder might be saved, which is a very considerable object. But important as this saving may be, it seems to be still exceeded by that of the article of the guns; for thus a small gun may be made to have the effect and execution of another of two or three times its size in the present mode, by discharging a shot of two or three times the weight of its natural ball or round shot. And thus a small ship might discharge shot as heavy as those of the greatest now made use of.

“ Finally, as the above experiments exhibit the regulations with regard to the weights of powder and balls, when fired from the same piece of ordnance, &c; so by making similar experiments with a gun, varied in its length, by cutting off from it a certain part before each course of experiments, the effects and general rules for the different lengths of guns may be certainly determined by them. In short, the principles on which these experiments were made, are so fruitful in consequences, that, in conjunction with the effects resulting from the resistance of the medium, they seem to be sufficient for answering all the inquiries of the speculative philosopher, as well as those of the practical artillerist.

In the year 1786 was published the first volume of my Tracts, in which is detailed, at great length, another very extensive course of experiments which were carried on at Woolwich, in the years 1783, 1784, and 1785, by order of the Duke of Richmond, master-general of the ordnance. The objects of this course were very numerous, but the principal of them were the following:

“ 1. The velocities with which balls are projected by equal charges of powder, from pieces of the same weight and caliber, but of different lengths.

“ 2. The velocities with different charges of powder, the weight and length of the gun being the same.

“ 3. The greatest velocity due to guns of different lengths, to be obtained by increasing the charge as far as the resistance of the piece is capable of sustaining.

“ 4. The effect of varying the weight of the piece; every thing else being the same.

“ 5. The penetration of balls into blocks of wood.

“ 6. The ranges and times of flight of balls; to compare them with their initial velocities, for determining the resistance of the medium.

“ 7. The effect of wads; of different degrees of ramming; of different degrees of windage; of different positions of the vent;

of chambers, and trunnions, and every other circumstance necessary to be known for the improvement of artillery.”

All these objects were obtained in a very perfect and accurate manner; excepting only the article of ranges, which were not quite so regular and uniform as might be wished. The balls were most of them of one pound weight; but the powder was increased from 1 ounce, up till the bore was quite full; and the pendulum was from 600 to 800lb. weight. The conclusions from the whole were as follow:

“ 1. That the former law, between the charge and velocity of ball, is again confirmed, viz, that the velocity is directly as the square root of the weight of powder, as far as to about the charge of 8 ounces: and so it would continue for all charges, were the guns of an indefinite length. But as the length of the charge is increased, and bears a more considerable proportion to the length of the bore, the velocity falls the more short of that proportion.

“ 2. That the velocity of the ball increases with the charge to a certain point, which is peculiar to each gun, where it is greatest; and that by farther increasing the charge, the velocity gradually diminishes, till the bore is quite full of powder. That this charge for the greatest velocity is greater as the gun is longer, but not greater however in so high a proportion as the length of the gun is; so that the part of the bore filled with powder bears a less proportion to the whole in the long guns, than it does in the short ones; the part of the whole which is filled being indeed nearly in the reciprocal subduplicate ratio of the length of the empty part. And the other circumstances as in this table.

Charges producing the Greatest Velocity.

Gun .Number	Length of the bore. inches.	Length filled. inches.	Part of the whole. $\frac{1}{2}$ $\frac{4}{5}$ $\frac{4}{5}$ $\frac{2}{3}$	Wt: of the powder. oz.
1	28·5	8·2	$\frac{1}{2}$	12
2	38·4	9·5	$\frac{4}{5}$	14
3	57·7	10·7	$\frac{4}{5}$	16
4	80·2	12·1	$\frac{2}{3}$	18

“ 3. It appears that the velocity continually increases as the gun is longer, though the increase in velocity is but very small in respect of the increase in length, the velocities being in a ratio somewhat less than that of the square roots of the length of the bore, but somewhat greater than that of the cube roots of the length, and is indeed nearly in the middle of the ratio between the two.

“ 4. The range increases in a much less ratio than the velocity, and indeed is nearly as the square root of the velocity, the gun and elevation being the same. And when this is compared with the property of the velocity and length of gun in the foregoing paragraph, we perceive that very little is gained in the range by a great increase in the length of the gun, the charge being the same. And indeed the range is nearly as the $\sqrt[5]{}$ root of the length of the bore; which is so small an increase, as to amount only to about $\frac{1}{4}$ th part more range for a double length of gun.

“ 5. It appears that the time of the ball's flight is nearly as the range; the gun and elevation being the same.

“ 6. It appears also that there is no sensible difference caused in the velocity or range, by varying the weight of the gun, nor by the use of wads, nor by different degrees of ramming, nor by firing the charge of powder in different parts of it.

" 7. But a great difference in the velocity arises from a small degree of windage. Indeed with the usual established windage only, namely, about $\frac{1}{20}$ th of the caliber, no less than between $\frac{1}{2}$ and $\frac{1}{4}$ of the powder escapes and is lost. And as the balls are often smaller than that size, it frequently happens that half the powder is lost by unnecessary windage.

" 8. It appears that the resisting force of wood, to balls fired into it, is not constant. And that the depths penetrated by different velocities or charges, are nearly as the logarithms of the charges, instead of being as the charges themselves, or, which is the same thing, as the square of the velocity.

" 9. These, and most other experiments, show that balls are greatly deflected from the direction they are projected in; and that so much as 300 or 400 yards in a range of a mile, or almost $\frac{1}{2}$ of the range, which is nearly a deflection of an angle of 15 degrees.

" 10. Finally, these experiments furnish us with the following concomitant data, to a tolerable degree of accuracy; namely, the dimensions and elevation of the gun, the weight and dimensions of the powder and shot, with the range and time of flight, and the first velocity of the ball. From which it is to be hoped that the measure of the resistance of the air to projectiles, may be determined, and thereby lay the foundation for a true and practical system of gunnery, which may be as well useful in service as in theory."

Since the publication of those Tracts, we have prosecuted the experiments still farther, from year to year, gradually extending our aim to more objects, and enlarging the guns and machinery, till we have arrived at experiments with the 6-pounder guns, and pendulums of 1800 pounds weight. One of the new objects of inquiry, was the resistance the atmosphere makes to military projectiles; to obtain which, the guns have been placed at many different distances from the pendulum, against which they are fired, to get the velocity lost in passing through those spaces of air; by which, and the use of the whirling machine, described in my new Tracts, vol. 3, for the slower motions, I have investigated the resistance of the air to given balls moving with all degrees of velocity, from 0 up to 2200 feet per second; as well as the resistance for many degrees of velocity, to planes and figures of other shapes, and inclined to their path in all varieties of angles; from which I have deduced general laws and formulas for all such motions.

Mr. Robins made also similar experiments on the resistance of the air; but being only with musket bullets, on account of their smallness, and of their change of figure by the explosion of the powder, I find they are very inaccurate, and considerably different from those above mentioned, which were accurately made with pretty considerable cannon balls, of iron. For which reason we may omit here the rules and theory deduced from them by Mr. Robins, till others more correct shall have been established. All these experiments indeed agree in evincing the very enormous resistance the air makes to the swift motions of military projectiles, amounting in some cases to 20 or 30 times the weight of the ball itself; on which account the common rules for projectiles, deduced from the parabolic theory, are of little or no use in real practice; for, from these experiments it is clearly proved, that the track described by the flight even of the heaviest shot, is neither a parabola, nor yet approaching any thing near it, except

when they are projected with very small velocities; in so much that some balls, which in the air range only to the distance of one mile, would in vacuo, when projected with the same velocity, range above 10 or 20 times as far. For the common rules of the parabolic theory, see PROJECTILES. See also the articles FORCE, and RESISTANCE, in this Dictionary.

Mr. Benjamin Thompson (now Count Rumford), instituted a very considerable course of experiments of the same kind as those of Mr. Robins, with musket barrels, which was published in the Philos. Trans. vol. 71, for the year 1781. In these experiments, the conclusions of Mr. Robins are generally confirmed, and several other curious circumstances in this business are at the same time remarked by Mr. Thompson. This gentleman also pursues a hint thrown out by Mr. Robins relative to the determining the velocity of a ball from the recoil of the pendulous gun itself. Mr. Robins, in prop. 11, remarks that the effect of the exploded powder upon the recoil of the gun, is the same, whether the gun is charged with a ball, or without one; and that the chord, or velocity, of recoil with the powder alone, being subtracted from that of the recoil when charged with both powder and ball, leaves the velocity which is due to the ball alone. Hence Mr. Thompson observes, that the inference is obvious, viz., that the momentum thus communicated to the gun by the ball alone, being equal to the momentum of the ball, this becomes known; and therefore being divided by the known weight of the ball, the quotient will be its velocity. Mr. Thompson sets a great value on this new rule, the velocities by means of which, he found to agree nearly with several of those deduced from the motion of the pendulum; and in the other cases in which they differed greatly from these, he very inconsistently supposes that these latter ones are erroneous. In the experiments however contained in my Tracts, a great multitude of those cases are compared together, and the inaccuracy of that new rule is fully proved.

Having in the 9th prop. compared together a number of computed and experimental velocities of balls, to verify his theory; in the 10th prop. Mr. Robins assigns the changes in the force of powder, which arise from the different state of the atmosphere, as to heat and moisture, both which he finds have some effect on it, but especially the latter. In prop. 11 he investigates the velocity which the flame of gunpowder acquires by expanding itself, supposing it fired in a given piece of artillery, without either a bullet or any other body placed before it. This velocity he finds is upwards of 7000 feet per second. But the celebrated Euler, in his commentary on this part of Mr. Robins's book, thinks it may be still much greater. And in this prop. it is that Mr. Robins declares his opinion, above alluded to, viz., that the effect of the powder upon the recoil of the gun is the same, in all cases, whether fired with a ball, or without one.—In prop. 12 he ascertains the manner in which the flame of powder impels a ball which is laid at a considerable distance from the charge; showing here that the sudden accumulation and density of the fluid against the ball, is the reason that the barrel is so often burst in those cases.—In prop. 13 he enumerates the various kinds of powder, and describes the properest methods of examining its goodness. He here shows that the best proportion of the ingredients, is when the saltpetre is $\frac{2}{3}$ of the whole compound mass of the powder, and the sulphur and charcoal the other $\frac{1}{3}$ between

them, in equal quantities. In this prop. Mr. Robins takes occasion to remark upon the use of eprouvettes, or methods of trying powder; condemning the practice of the English in using what is called the vertical eprouvette; as well as that of the French, in employing a small mortar, with a very large ball, and a small charge of powder: and instead of these, he strongly recommends the use of his ballistic pendulum, for its great accuracy: but for still greater dispatch, he tells us he should use another method, which however he reserves to himself, without giving any particular description of it. From what has been done by Mr. Robins upon this head, several persons have introduced his method of suspending the gun as a pendulum, and noting the quantity of its oscillating recoil when fired with a certain quantity of powder; and of this kind I have contrived a machine, which possesses several advantages over all others, being extremely simple, accurate, and expeditious; so much so indeed, that the weighing out of the powder is the chief part of the trouble. See GUNPOWDER, and EPROUVEETTE.

The other or 2d chapter of Mr. Robins's work, in 8 propositions, treats "of the resistance of the air, and of the track described by the flight of shot and shells." And of these, prop. 1 describes the general principles of the resistance of fluids to solid bodies moving in them. Here Mr. Robins discriminates between continued and compressed fluids, which immediately rush into the space quitted by a body moving in them, and whose parts yield to the impulse of the body without condensing and accumulating before it; and such fluids as are imperfectly compressed, rushing into a void space with a limited velocity, as in the case of our atmosphere, which condenses more and more before the ball as this moves quicker, and also presses the less behind it, by following it always with only a given velocity: hence it happens that the former fluid will resist moving bodies in proportion to the square of the velocity, while the latter resists in a higher proportion.—Proposition 2 is "to determine the resistance of the air to projectiles by experiments." One of the methods for this purpose, is by the ballistic pendulum, placing the gun at different distances from it, by which he finds the velocity lost in passing through certain spaces of air, and consequently the force of resistance to such velocities as the body moves with in the several parts of its path. And another way was by firing balls, with a given velocity, over a large piece of water, in which the fall and plunge of the ball could be seen, and consequently the space it passed over in a given time. By these means Mr. Robins determined the resistances of the air to several different velocities, all which showed that there was a gradual increase of the resistance, over the law of the square of the velocity, as the body moved quicker. In the remaining propositions of this chapter, he proceeds a little further in this subject of the resistance of the air; in which he lays down a rule for the proportion of the resistance between two assigned velocities; and he shows that when a 24-pound ball, fired with its full charge of powder, first issues from the piece, the resistance it meets with from the air is more than 20 times its weight. He further proves that "the track described by the flight of shot or shells is neither a parabola, nor nearly a parabola, unless they are projected with small velocities;" and that "bullets in their flight are not only depressed beneath their original direction by the action of gravity, but are also frequently driven to the right or left of that direction by the action

of some other force: and in the 8th or last proposition, he pretends to show that the depths of penetration of balls into firm substances, are as the squares of the velocities. But this is a mistake; for neither does it appear that his trials were sufficiently numerous or various, nor were his small leaden balls fit for this purpose; and I have found, from a number of trials with iron cannon balls, that the penetrations are in a much lower proportion, and that the resisting force of wood is not uniform. See my TRACTS.

In the following small tracts, added to the principles, in this volume, Mr. Robins prosecutes the subject of the resistance of the air much further, and lays down rules for computing ranges made in the air. But these must be far from accurate, as they are founded on the two following principles, which I know, from numerous experiments, are erroneous: viz, 1st, "That till the velocity of the projectile surpasses that of 1100 feet in a second, the resistance may be esteemed to be in the duplicate proportion of the velocity." 2d, That if the velocity be greater than that of 11 or 1200 feet in a second, then the absolute quantity of that resistance in these greater velocities will be near 3 times as great, as it should be by a comparison with the smaller velocities." For, instead of passing at once from the law of the square of the velocities, and ever after being about 3 times as much, my experiments prove that the increase of the resistance above the law of the square of the velocity, takes place at first in the smallest motions, and increases gradually more and more, to a certain point, but never rises so high as to be 3 times that quantity, after which it decreases again. All which fully appears in the 3d vol. of my new Tracts, lately published.

The additional tracts of Mr. Robins, in the latter part of this volume, which contain many useful and important matters, are numbered and titled as follows, viz. Number 1, "Of the resistance of the air. Number 2, Of the resistance of the air; together with the method of computing the motions of bodies projected in that medium. Number 3, An account of the experiments, relating to the resistance of the air, exhibited at different times before the Royal Society, in the year 1746. Number 4, Of the force of fired gunpowder, together with the computation of the velocities thereby communicated to military projectiles. Number 5, A comparison of the experimental ranges of cannon and mortars with the theory contained in the preceding papers.—Practical Maxims relating to the effects and management of artillery, and the flight of shells and shot.—A proposal for increasing the strength of the British navy, by changing all the guns, from the 18-poundsers downwards, into others of equal weight, but of a greater bore." With several letters, and other papers, "On pointing, or the directing of cannon to strike distant objects; Of the nature and advantage of rifled barrel-pieces," &c.

I have dwelt thus long on Mr. Robins's New Principles of Gunnery, because it is the first work that can be considered as attempting to establish a practical system of gunnery, and projectiles, on good experiments, on the force of gunpowder, on the resistance of the air, and on the effects of different pieces of artillery. Those experiments are however not sufficiently perfect, both on account of the smallness of the bullets, and for want of good ranges, to form a proper theory upon. I have supplied some of the necessary desiderata for this purpose, viz, the resistance of the air to cannon balls moving with all degrees of velocity, and the velocities communicated by given charges of powder to different balls, and from different pieces of

artillery. But there are still wanting good experiments with different pieces of ordnance, giving the ranges and times of flight, with all varieties of charges, and at all different angles of elevation. A few however of those I have obtained, as in the following small table, which are derived from experiments made with a medium one-pounder gun, the iron ball being nearly 2 inches in diameter.

Powder.	Elevation of gun.	Velocity of ball.	Range.	Time of flight.
oz	"	feet	feet	"
2	15	860	4100	9
4	15	1230	5100	12
8	15	1640	6000	14½
12	15	1680	6700	15½
2	45	860	5100	21

The celebrated Euler added many excellent dissertations on the subject of gunnery, in his translation of Robins's gunnery into the German language; which were again farther improved in Brown's translation of the same into English in the year 1777. See also Antoni's Examen de la Poudre; the experiments of MM. d'Arcy and Le Roy, in the Memoirs of the Academy in 1751; and D'Arcy's *Essai d'une théorie d'artillerie* in 1760: my Tracts; and paper on the force of fired gunpowder in the Philos. Trans. for 1778: and Thompson's paper on the same subject in 1781: but above all, vol. 2 and 3 of my new Tracts, containing the concluding deductions drawn from all the experiments made at Woolwich.

Of the common or parabolic theory of gunnery, Mr. Simpson gave a very neat and concise treatise in his Select Exercises. And a very ingenious treatise was also given by Mr. Reuben Burrough, in 1779; containing, not only the problems that are common on this subject, and the method of determining the maximum range on an inclined plane when the piece is situated in that plane; but also when it is placed above or below the given plane; a problem of much greater difficulty, and which had not before been publicly given by any other author. Other writers on this part, are Starrat, Gray, Williams, Glenie, &c.

GUNPOWDER, a composition of nitre, sulphur, and charcoal, mixed together, and usually granulated. This easily takes fire; and when fired, it rarefies or expands with great vehemence, by means of its elastic force.—It is to this powder that we owe all the effect and action of guns, and ordnance of all sorts. So that fortification, with the modern military art, &c, in a great measure depend upon it. The above definition however is not general, for instead of the nitre, it has lately been discovered that the marine acid answers much better, as to strength, but is dangerous in its use, as too liable to accidental explosion.

The invention of gunpowder is ascribed, by Polydore Virgil, to a chemist; who having accidentally put some of this composition in a mortar, and covered it with a stone, it happened to take fire, and blew up the stone. Thévet informs us that the person here spoken of was a monk of Fribourg, named Constantine Anelzen; but Belleforet and other authors, with more probability, hold it to be Bartholdus Schwartz, or Black, who discovered it, as some say, about the year 1320; and the first use of it is ascribed to the Venetians, in the year 1380, during the war with the Genoese. But there are earlier accounts of its use, after the accident of Schwartz, as well as before it.

VOL. I.

For Peter Mexia, in his Various Readings, mentions that the Moors being besieged in 1343, by Alphonso the 11th, king of Castile, discharged a kind of iron mortars upon them, which made a noise like thunder; and this is seconded by what is related by Don Pedro, bishop of Leon, in his chronicle of King Alphonso, who reduced Toledo, viz, that in a sea-combat between the king of Tunis and the Moorish king of Seville, about that time, those of Tunis had certain iron tubs or barrels, with which they threw thunderbolts of fire. Ducange adds, that there is mention made of gunpowder in the registers of the chambers of accounts in France as early as the year 1338.

But it appears that Roger Bacon knew of gunpowder near 100 years before Schwartz was born. He tells us, in his *Treatise De Secretis Operibus Artis et Naturæ, et de Nullitate Magiae*, cap. 6, (which is supposed by some to have been published at Oxford in 1216, and which was undoubtedly written before his *Opus Majus*, in 1267), "that from saltpetre, and other ingredients, we are able to make a fire that shall burn at what distance we please." Dr. Plot also in his *History of Oxfordshire*, pa. 236, assures us that these "other ingredients were explained in a MS. copy of the same treatise, in the hands of Dr. G. Langbain, and seen by Dr. Wallis, to be sulphur and wood coal." In addition to which we are told in the life of Friar Bacon in *Biographia Britannica*, vol. 1, that Bacon himself has divulged the secret of this composition in a cipher, by transposing the letters of the two words in chap. xi. of the said treatise; where it is thus expressed: sed tamen salis petras LURA MOPE CAN UBRE (i. e. carbonum pulvere) et sulphuris; et sic facies tonitrum et corruscationem, si scias artificium: and hence the biographer apprehends the words *carbonum pulvere* were transferred to the 6th chapter of Langbain's ms. In this same chapter Bacon expressly says that sounds like thunder, and corruscations, may be formed in the air, much more horrible than those that happen naturally. And farther adds, that there are many ways of doing this, by which a city or an army might be destroyed: and he supposes that by an artifice of this kind Gideon defeated the Midianites with only 300 men: Judges, chap. 7. There is also another passage to the same purpose, in the treatise *De Scientia Experimentali*. See Dr. Jebb's edition of the *Opus Majus*, pa. 474. See also the life of R. BACON in this Dictionary.

Mr. Robins, in the preface to his gunnery, apprehends that Bacon describes gunpowder not as a new composition first proposed by himself, but as the application of an old one to military purposes, and that it was known long before his time.

But M. Dutens carries the antiquity of gunpowder still much higher, and refers to the writings of the ancients themselves for the proof of it. "Virgil," says he, "and his Commentator Servius (*Aeneid*, lib: 6, v. 585), Hyginus (*Fabul. 61* and *650*), Eustathius (*ad Odys. 234*, pa. 1682, lib. 1), La Cerda (in Virgil, loc. cit.), Valerius Flaccus (lib. i. 662), and many other authors (as Raphael Volaterran, in *Commentarij Cornelii Agrippa poster. Oper. de Verbo Dei*, c. 100, pa. 237).—Gruteri *Fax Artium Liber.* tom. 2, pa. 1236), speak in such a manner of Salomonœus's attempts to imitate thunder, as suggest to us that this prince used for that purpose a composition of the nature of gunpowder. Eustathius in particular mentions him on this occasion, as being so very expert in mechanics, that he formed machines, which imitated the noise of thunder; and the writers of fable, whose surprise in this

4 K

respect may be compared to that of the Mexicans when they first beheld the fire-arms of the Spaniards, give out that Jupiter, incensed at the audacity of this prince, slew him with lightning, as he was employing himself in launching his thunder. But it is much more natural to suppose that this unfortunate prince, the inventor of gunpowder, gave rise to these fables, by having accidentally fallen a victim to his own experiments. Dion (Hist. Rom. in Caligula, pa. 662) and Joannes Antiochenus (in Chronico, &c. a Valesio edita, Paris 1634, pa. 804), report the very same thing of Caligula, assuring us that this emperor imitated thunder and lightning by means of certain machines, which at the same time emitted stones. Themistius also informs us that the Brachmans encountered one another with thunder and lightning, which they had the art of launching from on high at a considerable distance; (Themist. Oratio 27, pa. 337). And in another place he relates, that Hercules and Bacchus, attempting to assail them in a fort where they were entrenched, were so roughly received by reiterated strokes of thunder and lightning, that they were obliged to retire, leaving behind them an everlasting monument of the rashness of their enterprise. Agathias the historian reports of Anthemius Trabiensis, that having disagreed with his neighbour Zeno the rhetorician, he set fire to his house with thunder and lightning. It appears from all these passages, that the effects ascribed to these engines of war, especially those of Caligula, Anthemius, and the Indians, could be only brought about by gunpowder. And what is still more, we find in Julius Africanus a receipt for an ingenious composition to be thrown upon an enemy, which very nearly resembles that powder. But what places this beyond all doubt, is a clear and positive passage of an author called Marcus Gracius, whose work in manuscript is in the royal library at Paris, entitled Liber Ignium. Dr. Mead had the same also in manuscript, and a copy of that is now in my hands. (See above.) The author describes several ways of encountering an enemy, by launching fire upon him; and among others gives the following. Mix together one pound of live sulphur, two of charcoal of willow, and 6 of saltpetre; reducing them to a very fine powder in a marble mortar. He adds, that a certain quantity of this is to be put into a long, narrow, and well compacted cover, and so discharged into the air. Here we have the description of a rocket. The cover with which thunder is imitated, he represents as short, thick, but half-filled, and strongly bound with packthread; which is exactly the form of a cracker. He then treats of different methods of preparing the match, and how one squib may set fire to another in the air, by having it inclosed within it. In short, he speaks as clearly of the composition and effects of gunpowder, as any person in our times could do. I own I have not yet been able precisely to determine when this author lived, but probably it was before the time of the Arabian physician Mesue, who mentions him, and who flourished in the beginning of the 9th century. Nay, there is reason to believe that he is the same of whom Galen speaks; in which case he will be of antiquity sufficient to support what I advance." It appears also from many authors, and many circumstances, that this composition has been known to the Chinese and Indians for thousands of years. See what is said on this head under the article GUN.

To this history of gunpowder it may be added, that it has lately been discovered that saltpetre or nitre is not es-

sential to this composition, but that its place may be supplied by other substances; for new gunpowder, of double the strength of the old, has lately been made in France, by the chemists in that country, without any nitre at all; and in the year 1790 I tried some of this new powder, that was made at Woolwich, with my eprouvette, when I found it about double the strength of the ordinary sort. This is effected by substituting, instead of the nitre, the like quantity of the marine acid.

But perhaps this new composition may not come into common and general use; both because of the great expense in procuring or making the acid, and of the trouble and danger of preventing it from taking fire by the heat in the operation; for it is found to catch fire and explode from a very small degree of heat, and without the aid of a spark.

As to the Preparation of GUNPOWDER; there are divers compositions of it, with respect to the proportions of the three ingredients, to be met with in pyrotechnical writings; but the process of making it up is much the same in all.

For some time after the invention of artillery, gunpowder was of a much weaker composition than that now in use, or that described by Marcus Gracius; which was chiefly owing to the weakness of their first pieces. See GUN and CANNON. Of 23 different compositions, used at different times, and mentioned by Tartaglia in his Ques. and Inv. lib. 3, ques. 5, the first, which was the oldest, contained equal parts of the three ingredients. But when guns of modern structure were introduced, gunpowder of the same composition as the present came also into use. In the time of Tartaglia the cannon powder was made of 4 parts of nitre, one of sulphur, and one of charcoal; and the musket powder of 48 parts of nitre, 7 parts of sulphur, and 8 parts of charcoal; or of 18 parts of nitre, 2 parts of sulphur, and 3 parts of charcoal. But the modern composition is 6 parts of nitre, to one of each of the other two ingredients. Though Mr. Napier says, he finds the strength commonly to be greatest when the proportions are, nitre 3lb., charcoal about 9oz, and sulphur about 3oz. See his paper on Gunpowder in the Transactions of the Royal Irish Academy, vol. 2. The cannon powder was in meal, and the musket powder grained. And it is certain that the graining of powder, which is a very considerable advantage, is a modern improvement. See the preface to Robins's Math. Tracts, pa. 32.

In making gunpowder, regard is to be had to the purity or goodness of the ingredients, as well as the proportions of them; for the strength of the powder depends much on that circumstance, and also on the proper working or mixing them together.

To purify the nitre, by taking away the fixt or common salt, and earthy part. Dissolve it in a quantity of hot water over the fire; then filtrate it through a flannel bag, into an open vessel, and set it aside to cool, and to crystallize. These crystals may in like manner be dissolved and crystallized again; and so on, till they become quite pure and white. Then put these crystals into a dry kettle over a moderate fire, which gradually increase till it begins to smoke, evaporate, lose its humidity, and grow very white: it must be kept continually stirring with a ladle, lest it should return to its former figure, by which its greasiness would be taken away: after that, so much water is to be poured into the kettle as will cover the nitre; and when it is dissolved, and reduced to the consistency of a thick liquor, it must be continually stirred with a ladle till all

the moisture is again evaporated, and it be reduced to a dry and white meal.

The like regard is to be had to the sulphur; choosing that which is in large lumps, clear and perfectly yellow; not very hard, nor compact, but porous; nor yet too much shining; and if, when set on fire, it freely burns all away, it is a sign of its goodness: so likewise, if it be pressed between two iron plates that are hot enough to make it run, and in the running it appears yellow, and that which remains of a reddish colour, it is then fit for the purpose. But in case it be foul, it may be purified in this manner: melt the sulphur in a large iron ladle, or pot, over a very gentle coal fire, well kindled, but not flaming; then scum off all that rises on the top, and swims upon the sulphur; take it presently after from the fire, and strain it through a double linen cloth, letting it pass leisurely; so will it be pure, the gross matter remaining behind in the cloth.

For the charcoal, the third ingredient, such should be chosen as is large, clear, and free from knots, well burnt, and cleaving. The charcoal of light woods is mostly preferred, as of willow, and that of the branches or twigs of a moderate thickness, as of an inch or two in diameter. Dogwood is now much esteemed for this purpose. And a method of charring the wood in a large iron cylinder has lately been recommended, and indeed proved, as yielding better charcoal than formerly. The charcoal not only concurs with the sulphur in supplying the inflammable matter, which causes the detonation of the nitre, but also greatly adds to the explosive power of it by the quantity of elastic vapour expelled during its combustion.

These three ingredients, in their purest state, being procured, long experience has shown that they are then to be mixed together in the proportion before mentioned, to have the best effect, viz. three-quarters of the composition to be nitre, and the other quarter made up of equal parts of the other two ingredients; or, which is the same thing, 6 parts nitre, 1 part sulphur, and 1 part charcoal.

But it is not the due proportion of the materials only, which is necessary to the making of good powder; another circumstance, not less essential, is the mixing them well together: if this be not effectually done, some parts of the composition will have too much nitre in them, and others too little; and in either case there will be a defect of strength in the powder. Robins, pa. 119.

After the materials have been reduced to fine dust, they are mixed together, and moistened with water, or vinegar, or urine, or spirit of wine, &c, and then beaten together with wooden pestles for 24 hours, either by hand, or by mills, and afterwards pressed into a hard, firm, and solid cake. When dry, it is grained or corned; which is done by breaking the cake of powder into small pieces, and so running it through a sieve; by which means the grains may have any size given them, according to the nature of the sieve employed, either finer or coarser; and thus also the dust is separated from the grains, and again mixed with other manufacturing powder, or worked again into cakes.

Powder is smoothed, or glazed, as it is called, for small arms, by the following operation: a hollow cylinder or cask is mounted on an axis, turned by a wheel; this cask is half filled with powder, and turned for 6 hours; and thus by the mutual friction of the grains of powder it is smoothed, or glazed. The fine mealy part, thus separated or worn off from the rest, is again granulated.

The Nature, Effects, &c, of Powder.—When the powder is prepared as above, if the least spark be struck upon it from a steel and flint, the whole will immediately inflame, and burst forth with extreme violence.—The effect is by no means difficult to account for: the charcoal part of the grain upon which the spark falls, catching fire like tinder, the sulphur and nitre are readily melted, and the former also breaks into flame; the contiguous grains at the same time undergoing the same decomposition.

Upon this point Sir Isaac Newton reasons thus: The charcoal and sulphur in gunpowder easily take fire, and kindle the nitre; and the spirit of the nitre, being thereby rarefied into vapour, rushes out with an explosion much after the manner that the vapour of water rushes out of an epiolite; the sulphur also, being volatile, is converted into vapour, and augments the explosion: add, that the acid vapour of the sulphur, namely that which distils under a bell into oil of sulphur, entering violently into the fixt body of the nitre, lets loose the spirit of the nitre, and excites a greater fermentation, by which the heat is farther augmented, and the fixt body of the nitre is also rarefied into fume; and the explosion in consequence made more vehement and quick.

For if salt of tartar be mixed with gunpowder, and that mixture be warmed till it takes fire, the explosion will be far more violent and rapid than that of gunpowder alone; which cannot proceed from any other cause, than the action of the vapour of the gunpowder upon the salt of tartar, by which that salt is rarefied.

The explosion of gunpowder therefore arises from the violent action, by which all the mixture being quickly and vehemently heated, is rarefied and converted into fume and vapour; which vapour, by the violence of that action becoming so hot as to shine, appears in the form of a flame.

M. Lahire, in the History of the French Academy for 1702, ascribes all the force and effect of gunpowder to the spring or elasticity of the air inclosed in the several grains of it, and in the intervals or spaces between the grains: the powder being kindled, sets the springs of so many little parcels of air into action, and dilates them all at once, whence the effect; the powder itself only serving to light a fire which may put the air in action; after which the whole is performed by the air alone.

But it appears from the experiments and observations of Mr. Robins, that if this air be in its natural state at the time when the powder is fired, the greatest addition its elasticity could acquire from the flame of the explosion, would not amount to five times its usual quantity, and therefore could not suffice for the 200th part of the effort which is exerted by fired powder. To understand the force of gunpowder, it must be considered that, whether it be fired in a vacuum or in air, it produces by its explosion a permanent elastic fluid. See Philos. Trans. No. 295; also Hauksbee's Phys. Mechan. Exp. pa. 81. It also appears from experiment, that the elasticity or pressure of the fluid produced by the firing of gunpowder, is, *ceteris paribus*, directly as its density.

In order to determine the elasticity and quantity of this elastic fluid, produced from the explosion of a given quantity of gunpowder, Mr. Robins premises, that the elasticity of this fluid increases by heat, and diminishes by cold, in the same manner as common air; and that the density of this fluid, and consequently its weight, is the same with the weight of an equal bulk of air, having the same elasticity and the same temperature. From these

principles, and from the experiments by which they are established (for a detail of which we must refer to the book itself, so often cited in the preceding articles), he concludes that the fluid produced by the firing of gunpowder is nearly $\frac{3}{5}$ of the weight of the generating powder itself; and that the volume or bulk of this air or fluid, when expanded to the rarity of common atmospheric air, is about 244 times the bulk of the said generating powder; and which I have proved to be 1600 times the bulk it occupied in the nitre (Tracts, vol. 3, pa. 303). Count Saluce, in his Miscel. Phil. Mathem. Soc. Priv. Taurin. pa. 125, makes the proportion as 222 to 1; which he says agrees with the computation of Mess. Hauksbee, Amontons, and Belidor.

Hence it appears, that any quantity of powder fired in any confined space, which it adequately fills, exerts at the instant of its explosion against the sides of the vessel containing it, and the bodies it impels before it, a force at least 244 times greater than the elasticity of common air, or, which is the same thing, than the pressure of the atmosphere; and this, without considering the great addition arising from the violent degree of heat with which it is endued at that time; the quantity of which augmentation is the next head of Mr. Robins's enquiry. He determines that the elasticity of the air is increased in a proportion somewhat greater than that of 4 to 1, when heated to the extremest heat of red hot iron; and supposing that the flame of fired gunpowder is not of a less degree of heat, increasing the former number a little more than 4 times, makes nearly 1000; which shows that the elasticity of the flame, at the moment of explosion, is about 1000 times stronger than the elasticity of common air, or than the pressure of the atmosphere. But, from the height of the barometer, it is known that the pressure of the atmosphere upon every square inch, is on a medium 14 $\frac{1}{2}$ lb; and therefore 1000 times this, or 14750lb, is the force or pressure of the flame of gunpowder, at the moment of explosion, upon a square inch, which is very nearly equivalent to 6 tons and a half. And it is proved in my Tracts, vol. 3, that the force is more than double of this. This great force however diminishes as the fluid dilates itself, and in that proportion, viz, in proportion to the space it occupies, it being only half the strength when it occupies a double space, one third the strength when triple the space, and so on.

Mr. Robins further supposes the degree of heat above mentioned to be a kind of medium heat; but that in the case of large quantities of powder the heat will be higher, and in very small quantities lower; and that therefore in the former case the force will be somewhat more, and in the latter somewhat less, than 1000 times the force or pressure of the atmosphere.

He further found that the strength of powder is the same in all variations in the density of the atmosphere. But that the moisture of the air has a great effect upon it; for the same quantity which in a dry season would discharge a bullet with a velocity of 1700 feet in one second, will not in damp weather give it a velocity of more than 12 or 1300 feet in a second, or even less, if the powder be bad, and improperly kept. Robins's Tracts, vol. 1, pa. 101, &c. Farther, as there is a certain quantity of water which, when mixed with powder, will prevent its firing at all, it cannot be doubted but every degree of moisture must abate the violence of the explosion; and hence the effects of damp powder are not difficult to be accounted for.

It is to be observed, however, that the moisture imbibed by powder does not render it less active when dried again. Indeed, if powder be exposed to very great damps without any caution, or when common salt abounds in it, as often happens through negligence in refining the nitre, in such cases the moisture it imbibes may perhaps be sufficient to dissolve some part of the nitre: which is a permanent damage that no drying can retrieve. But when tolerable care is taken in preserving powder, and the nitre it is composed of has been well purged from common salt, it will retain its force for a long time; and it is said that powder has been known to have been preserved for 50 years without any apparent damage from its age.

The velocity of expansion of the flame of gunpowder, when fired in a piece of artillery, without either bullet or other body placed before it, is prodigiously great, viz, 7000 feet per second, or upwards, as appears from the experiments of Mr. Robins. But Mr. Bernoulli as well as Euler suspect it is still much greater; though I have found it to be much the same as Mr. Robins. See my Tracts, vol. 3, pa. 306.

It is this prodigious celerity of expansion of the flame of fired gunpowder, which is its peculiar excellence, and the circumstance in which it so eminently surpasses all other inventions, either ancient or modern: for as to the momentum of these projectiles only, many of the warlike machines of the ancients produced this in a degree far surpassing that of our heaviest cannon shot or shells; but the great celerity given to these bodies cannot be in the least approached by any other means than the flame of powder.

To prove Gunpowder. There are several ways of doing this. 1, By sight: thus, if it be too black, it is a sign that it is moist, or else that it contains too much charcoal; so also, if rubbed upon white paper, it blackens it more than good powder does: but if it be of a kind of azure colour, somewhat inclining to red, it is a proof of good powder. 2, By touching: for if in crushing it with the fingers' ends, the grains break easily, and turn into dust, without feeling hard, it has too much coal in it; or if, in pressing it under the fingers upon a smooth hard board, some grains feel harder than the rest, it denotes that the sulphur is not well mixed with the nitre. Also by thrusting the hand into the parcel of powder, and grasping it, as if to take out a handful, you will feel whether it be dry and equally grained, by its evading the grasp, and running mostly out of the hand. 3, By burning: and here the method most commonly followed for this purpose with us, says Mr. Robins, is to fire a small heap of it on a clean board, and to attend nicely to the flame and smoke it produces, as well as to the marks it leaves behind on the board: but besides this uncertain method, there are other contrivances made use of, such as powder-triers acting by a spring, commonly sold at the shops, and others again that move a great weight, throwing it upwards, which is a very bad sort of eprouvette. But these machines, says Mr. Robins, though more perfect than the common powder-triers, are yet liable to great irregularities; for as they are all moved by the instantaneous stroke of the flame, and not by its continued pressure, they do not determine the force of the fired powder with sufficient certainty and uniformity. Another method is to judge from the range given to a large solid ball, thrown from a very short mortar, charged with a small quantity of powder; which is also an uncertain way, both on account of the great disproportion between the weight of

the ball and powder, and the unequal resistance of the air; not to mention that it is too tedious to prove large quantities of powder in this way; for, "if each barrel of powder was to be proved in this manner, the trouble of charging the mortar, and bringing back the ball each time, would be intolerable, and the delay so great, that no business of this kind could ever be finished; and if a number of barrels are received on the merit of a few, it is great odds, but some bad ones would be among them, which may prove a great disappointment in time of service." These exceptions do "noways hold," continues Mr. Robins, "against the method by which I have tried the comparative strength of different kinds of powder, which has been by the actual velocity given to a bullet, by such a quantity of powder as is usually esteemed a proper charge for the piece; and as this velocity, however great, is easily discovered by the motion which the pendulum acquires from the stroke of the bullet, it might seem a good amendment to the method used by the French (viz, that of the small mortar above-mentioned) to introduce this trial by the pendulum instead of it. But though I am satisfied, that this would be much more accurate, less laborious, and readier than the other, yet, as there is some little attention and caution required in this practice, which might render it of less dispatch than might be convenient, when a great number of barrels were to be separately tried, I should myself choose to practise another method not less certain, but prodigiously more expeditious; so that I could engage, that the weighing out of a small parcel of powder from each barrel should be the greatest part of the labour; and doubtless three or four hands could, by this means, examine 500 barrels in a morning: besides, the machines for this purpose, as they might be made of cast-iron, would be so very cheap, that they might be multiplied at pleasure." Robins, page 123. It is not certainly known what might be the particular construction of the eprouvette here hinted at, but it was probably a piece of ordnance suspended like a pendulum, as he had made several experiments with a barrel in that manner. Be this however as it may, several persons, from those ideas and experiments of Mr. Robins, have made eprouvettes on this principle, which appears to be the best of any; and on this idea also I have lately made a machine for this purpose, which has several peculiar contrivances, and advantages over all others, both in the nature of its motion, and the divisions on its arc, &c. It is a small cannon, the bore of which is about one inch in diameter, and is usually charged with 2 ounces of powder, and with powder only, as a ball is not necessary, and the strength of the powder is accurately shown by the arc of the gun's recoil. The whole machine is so simple, easy, and expeditious, that, as Mr. Robins observed above, the weighing of the powder is the chief part of the trouble; and so accurate and uniform, that the successive repetitions or firings with the same quantity of the same kind of powder, seldom gave a difference in the recoil of the 100th part of itself. See the construction and use of this eprouvette in my Tracts, vol. 3, tract 35.

To recover damaged Powder. The method of the powder merchants is this: they put part of the powder on a sail-cloth, to which they add an equal weight of what is really good; then with a shovel they mingle it well together, dry it in the sun, and barrel it up, keeping it in a dry and proper place.

Others again, if it be very bad, restore it by moistening

it with vinegar, water, urine, or brandy; they then beat it fine, sift it, and to every pound of powder add an ounce, or an ounce and a half, or two ounces (according as it is decayed), of melted nitre; and afterwards these ingredients are to be moistened and well mixed, so that nothing may be discerned in the composition, which may be known by cutting the mass, and then they granulate it as useful.

In case the powder be quite spoiled, the only way is to extract the saltpetre with water, in the usual way, by boiling, filtrating, evaporating, and crystallizing; and then, with fresh sulphur and charcoal, to make it up again.

On the subject of gunpowder, see also Euler on Robins's Gunnery, Antoni Examen de la Poudre, Baumé's Chemistry, and Thompson's Experiments in the Philos. Trans. for 1781.

GUNTER (EDMUND), an excellent English mathematician, was born in Hertfordshire in 1581. He was educated at Westminster-school under Dr. Busby, and from thence was elected to Christ-church college, Oxford, in 1599, where he took the degree of master of arts in 1606, and afterwards entered into holy orders; and in 1615 he took the degree of bachelor of divinity. But being particularly distinguished for his mathematical talents, when Mr. Williams resigned the professorship of astronomy in Gresham-college, London, Mr. Gunter was chosen to succeed him, the 6th of March, 1619; where he greatly distinguished himself by his lectures and writings, and where he died in 1626, at only 45 years of age, to the great loss of the mathematical world.

Mr. Gunter was the author of many useful works and inventions. About the year 1606, he merited the title of an inventor, by the new projection of his Sector, which he then described in a Latin treatise, not printed however till some time afterwards.—In 1618 he had invented a small portable quadrant, for the more readily finding the hour and azimuth, and other useful purposes in astronomy.—And in 1620 or 1623, he published his *Canon Triangulorum*, or Table of Artificial Sines and Tangents, to the radius, 10,000,000 parts, to every minute of the quadrant, being the first tables of this kind published; together with the first 1000 of Briggs's logarithms of common numbers, which were in later editions extended to 10,000 numbers.—In 1622, he discovered, by experiment made at Deptford, the variation or changeable declination of the magnetic needle; his experiment showing that the declination had varied 5 degrees in the space of 42 years; and the same was confirmed and established by his successor Mr. Gellibrand.—He applied the logarithms of numbers, and of sines and tangents, to straight lines drawn on a scale or ruler; with which, proportions in common numbers and trigonometry were resolved, by the mere application of a pair of compasses; a method founded on this property, that the logarithms of the terms of equal ratios are equidifferent. This was called Gunter's Proportion, and Gunter's Line; and the instrument, in the form of a two-foot scale, is still in common use for navigation and other purposes, and is commonly called the Gunter. He also greatly improved the sector and other instruments, for the same uses; the description of all which he published in 1624.—He introduced the common measuring chain, now constantly used in land-surveying, which is thence called Gunter's chain.—Mr. Gunter drew the lines on the dials in Whitehall-garden, and wrote the description and use of them, by the direction of Prince Charles, in a small

tract; which he afterwards printed at the desire of King James, in 1624.—He was the first who used the word cosine, for the sine of the complement of an arc. He also introduced the use of arithmetical complements into the logarithmical arithmetic, as is witnessed by Briggs, cap. 15, Arith. Log. And it has been said that he first started the idea of the Logarithmic Curve, which was so called, because the segments of its axis are the logarithms of the corresponding ordinates.

His works have been collected, and various editions of them have been published; the 5th is by Mr. William Leybourne, in 1673, containing the Description and Use of the Sector, Cross-staff, Bow, Quadrant, and other instruments; with several pieces added by Samuel Foster, Henry Bond, and William Leybourne.

GUNTER'S CHAIN, the chain in common use for measuring land, according to true or statute measure; so called from Mr. Gunter its reputed inventor. The length of the chain is 66 feet, or 22 yards, or 4 poles of $5\frac{1}{2}$ yards each; and it is divided into 100 links, of 7'9 $\frac{1}{2}$ inches each. This chain is the most convenient of any instrument for measuring land, because the contents thence computed are so easily reduced to acres. The reason of which is, that an acre of land is just equal to 10 square chains, or 10 chains in length and 1 in breadth, or equal to 100,000 square links. Hence, the dimensions being taken in chains, and multiplied together, it gives the content in square chains; which therefore being divided by 10, or a figure cut off for decimals, brings the content to acres; after which the decimals are reduced to rods and perches, by multiplying by 4 and 40. But the better way is to set the dimensions down in links as integers, considering each chain as 100 links; then, having multiplied the dimensions together, producing square links, divide these by 100,000, that is, cut off five places for decimals, the rest are acres, and the decimals are reduced to rods and perches, as before.

Example. Suppose in measuring a rectangular piece of ground, its length be 795 links, and its breadth 480 links.

63600
3180
Ac. 3'81600
4
Ro. 3'264
40
Per. 10'560

So the content is 3 ac. 3 rods 10 perches.

GUNTER'S LINE, a Logarithmic line, usually graduated upon scales, sectors, &c.; and so called from its inventor Mr. Gunter. This is otherwise called the line of lines, or line of numbers, and consists of the logarithms transferred upon a ruler, &c., from the tables, by means of a scale of equal parts, which therefore serves to resolve problems instrumentally, in the same manner as logarithms do arithmetically. For, whereas logarithms resolve proportions, or perform multiplication and division, by only addition and subtraction, the same are performed on this line by turning a pair of compasses over this way or that, or by sliding one slip of wood by the side of another, &c.

A line of this description has been contrived various ways, for the advantage of having it as long as possible. As, first, on the two feet ruler or scale, by Gunter. Then,

in 1627 the logarithms were drawn by Wingate, on two separate rulers, sliding against each other, to save the use of compasses in resolving proportions. They were also in 1627 applied to concentric circles by Oughtred. Then in a spiral form by Mr. Milburne of Yorkshire, about the year 1650. Also, in 1657, on the present common sliding rule, by Seth Partridge.

Lastly, Mr. William Nicholson has proposed another disposition of them, on concentric circles, in the Philos. Trans. an. 1787, pa. 251. His instrument is equivalent to a straight rule of $28\frac{1}{2}$ inches long. It consists of three concentric circles, engraved and graduated on a plate of about $1\frac{1}{2}$ inch in diameter. From the centre proceed two legs, having right-lined edges in the direction of radii; which are moveable either singly, or together. To use this instrument; place the edge of one leg at the antecedent of any proportion, and the other at the consequent, and fix them to that angle: the two legs being then moved together, and the antecedent leg placed at any other number, the other leg gives its consequent in the like position or situation on the lines.

The whole length of the line is divided into two equal intervals, or radii, of 9 larger divisions in each radius, which are numbered from 1 to 10, the 1 standing at the beginning of the line, because the logarithm of 1 is 0, and the 10 at the end of each radius; also each of these 9 spaces is subdivided into 10 other parts, unequal according to the logarithms of numbers; the smaller divisions being always 10ths of the larger; thus, if the large divisions be units or ones, the smaller are tenth-parts; if the larger be tens, the smaller are ones; and if the larger be 100's, the smaller are 10's; &c.

Use of Gunter's Line. 1. *To find the product of two numbers.* Extend the compasses from 1 to either of the numbers, and that extent will reach the same way from the other number to the product. Thus, to multiply 7 and 5 together; extend the compasses from 1 to 5, and that extent will reach from 7 to 35, the product.

2. *To divide one number by another.* Extend the compasses from the divisor to 1, and that extent will reach the same way from the dividend to the quotient. Thus, to divide 35 by 5; extend the compasses from 5 to 1, and that extent will reach from 35 to 7, which is the quotient.

3. *To find a 4th proportional to three given numbers;* as suppose to 6, 9, and 10. Extend from 6 to 9, and that extent will reach from 10 to 15, which is the 4th proportional sought. In like manner, a 3d proportional is found to two given terms, extending from the 1st to the 2d, and then from the 2d to the 3d.

4. *To find a mean proportional between two given numbers,* as suppose between 7 and 28. Extend from 7 to 28, and bisect that extent; then its half will reach from 7 forward, or from 28 backward, to 14, the mean proportional between them.—Also, to extract the square root, as of 25, which is only finding a mean proportional between 1 and the given square 25, bisect the distance between 1 and 25, and the half will reach from 1 to 5, the root sought.—In like manner the cube or 3d root, or the 4th, 5th, or any higher root, is found, by taking the extent between 1 and the given power; then take such part of it as is denoted by the index of the root, viz. the 3d part for the cube root, the 4th part for the 4th root, and so on, and that part will reach from 1 to the root sought.

If the line on the scale or ruler have a slider, this is to be used instead of the compasses.

GUNTER'S QUADRANT, is a quadrant made of wood, brass, or some other substance; being a kind of stereographic projection on the plane of the equinoctial, the eye being supposed in one of the poles: so that the tropic, ecliptic, and horizon, form the arches of circles, but the hour circles other curves, drawn by means of several altitudes of the sun, for some particular latitude every day in the year.

The use of this instrument, is to find the hour of the day, the sun's azimuth, &c, and other common problems of the sphere or globe; as also to take the altitude of an object in degrees. See **QUADRANT**.

GUNTER'S SCALE, usually called by seamen The Gunter, is a large plain scale, having various lines upon it of great use in working the cases or questions in Navigation. This scale is usually 2 feet long, and about an inch and a half broad, with various lines upon it, both natural and logarithmic, relating to trigonometry, and navigation, &c.

On the one side are the natural lines, and on the other the artificial or logarithmic ones. The former side is first divided into inches and tenths, and numbered from 1 to 24 inches, running the whole length near one edge. One half the length of this side consists of two plane diagonal scales, for taking off dimensions to three places of figures. On the other half or foot of this side, are contained various lines relating to trigonometry, in the natural numbers, and marked thus, viz,

Rumb. the rumbs or points of the compass,
Chord. the line of chords,
Sine. the line of sines,
Tang. the tangents,
S. T. the semitangents,
and at the other end of this half are
Leag. leagues, or equal parts,
Rumb. another line of rumbs;

M. L. miles of longitude,
Chor. another line of chords.

Also in the middle of this foot are *L.* and *P.* two other lines of equal parts. And all these lines, on this side of the scale, serve for drawing or laying down the figures to the cases in trigonometry and navigation.

On the other side of the scale are the following artificial or logarithmic lines, which serve for working or resolving those cases; viz,

S. R. the sine rumbs,
T. R. the tangent rumbs,
Numb. line of numbers,
Sine. Sines,
V. S. the versed sines,
Tang. the tangents,
Meriz. Meridional parts,
E. P. Equal parts.

The late Mr. John Robertson, clerk and librarian to the Royal Society, greatly improved this scale, both as to size and accuracy, for the use of mariners. He extended it to 30 inches long, 2 inches broad, and half an inch thick; upon which the several lines are very accurately laid down by Messrs. Nairne and Blunt, ingenious instrument makers. Mr. Robertson died before his improved scales were published; but the account and description of them were supplied and drawn up by his friend Mr. William Mountaine, and published in 1778.

GUTTÆ, or *Drops*, in Architecture, are ornaments in form of little bells or cones, used in the Doric order, on the architrave, below the triglyphs. There are usually six of them.

GYMNOSEPHISTS, a set of Indian philosophers, famous in antiquity; so denominated from their going barefoot; as that of Peripatetics was given to those who philosophized walking.

HADLEY (John), a distinguished member of the Royal Society, was elected a fellow in 1717, and died Feb. 15, 1744. He contributed many useful papers to the Royal Society, which are contained in their Trans. from vol. 32 to vol. 39 inclusive. But he has been chiefly celebrated for the invention of his reflecting instrument for taking angles, commonly called the Hadley's Quadrant or Sextant, offered to the Royal Society in 1731, by which his name has been rendered immortal.

HADLEY'S Quadrant, Sextant, &c, an excellent instrument so called from its inventor John Hadley, esq. See its description and use under the article **QUADRANT**.

HAIL, or **HAILSTONES**, an aqueous concretion, usually in form of white or pellucid spherules, descending out of the atmosphere. Hailstones assume various shapes, being sometimes round, at other times pyramidal, crenated, angular, thin, and flat, and sometimes stellated, with six radii like the small crystals of snow.

It is very difficult to account for the phenomena of hail in a satisfactory manner; and there are various opinions on this head. It is usually conceived that hail is formed of drops of rain, frozen in their passage through the mid-

dle region. Others, as the Cartesians, take it for the fragments of a frozen cloud, half melted, and thus precipitated and congealed again. Signor Beccaria supposes, that it is formed in the higher regions of the air, where the cold is intense, and where the electric matter is very copious. In these circumstances, a great number of particles of water are brought near together, where they are frozen, and in their descent they collect other particles; so that the density of the substance of the hailstone becomes less and less, from the centre; this being formed first in the higher regions, and the surface being collected in the lower. Accordingly, in mountains, hailstones as well as drops of rain, are very small; and both agree in this circumstance, that the more intense the electricity is that forms them, the larger they are. It is frequently observed that hail attends thunder and lightning; and hence Beccaria observes, that as motion promotes freezing, so the rapid motion of the electrified clouds may promote that effect in the air. Natural histories furnish us with a great variety of curious instances of extraordinary showers of hail. See the Philos. Trans. No. 203, 229; and Hist. de France, tom. 2, pa. 33

HALF-MOON, in Fortification, is an outwork having only two faces, forming together a salient angle, which is flanked by some part of the place, and of the other bastions. See **DEMILUNE** and **RAVELIN**.

HALF-TANGENTS, are the tangents of the half arcs. See **SCALE** and **SEMITANGENTS**.

HALLEY (Dr. EDMUND), a most eminent English mathematician, philosopher and astronomer, was born in the parish of St. Leonard, Shoreditch, near London, Oct. 29, 1656. His father, a wealthy citizen and soap-boiler, resolving to improve the promising disposition observed in his son, put him first to St. Paul's school, where he soon excelled in all parts of classical learning, and made besides a considerable advance in the mathematics; so that, as Wood observes, he had perfectly learnt the use of the celestial globe, and could make a complete dial; and we are informed by Halley himself, that he observed the change of the variation of the magnetic needle at London in 1672, one year before he left school. In 1673 he was sent to Oxford, where he chiefly applied himself to mathematics and astronomy, in which he was greatly assisted by a curious apparatus of instruments, which his father, willing to encourage his son's genius, had purchased for him. At 19 years of age he began to oblige the world with new observations and discoveries (which he continued to do to the end of a very long life), by publishing "A Direct and Geometrical Method of finding the Aphelion and Excentricity of the planets." Besides various particular observations, made from time to time on the celestial phenomena; he had, from his first admission into college, pursued a general scheme for ascertaining the true places of the fixed stars, and by this means to correct the errors of Tycho Brahe. His original view in this was, to carry on the design of that first restorer of astronomy, by completing the catalogue of those stars from his own observations; but, on further inquiry, finding this province taken up by Hevelius and Flamsteed, he dropped that pursuit, and formed another; which was, to perfect the whole scheme of the heavens, by the addition of the stars which lie so near the south pole, that they could not be observed by those astronomers, as never rising above the horizon either at Dantzick or at Greenwich. With this intention he left the University, before he had taken any degree, and embarked for the island of St. Helena in Nov. 1676, when he was only 20 years of age, and arrived there after a voyage of three months. He immediately set about his task with such diligence, that he completed his catalogue, and, returning home, landed in England in Nov. 1678, after an absence of two years only. The university of Oxford immediately conferred upon him the degree of A. M. and the Royal Society of London elected him one of their members.

In 1679 he was selected by the Royal Society to go to Dantzick, to endeavour to adjust a dispute between Hevelius and Mr. Hooke, concerning the preference between plain and glass sights, in astroscopic instruments. He arrived at Dantzick the 26th of May, when he immediately, in conjunction with Hevelius, set about their astronomical observations, which they closely continued till the 18th of July, when Halley left Dantzick, and returned to England.

In the year 1680 he undertook what is called the grand tour, accompanied by his friend the celebrated Mr. Nelson. In the way from Calais to Paris, Mr. Halley had a sight of a remarkable comet, as it then appeared a second

time that year, in its return from the sun. He had, the November before, seen it in its descent: and he now hastened to complete his observations upon it, by viewing it from the royal observatory of France. His design in this part of his tour was, to settle a friendly correspondence between the two royal astronomers of Greenwich and Paris; and in the mean time to improve himself under so great a master as Cassini. From thence he went to Italy, where he spent a great part of the year 1681; but his affairs calling him home, he then returned to England.

Soon after his return, he married the daughter of Mr. Tooke, auditor of the exchequer, and took up his residence at Islington, where he set up his tube and sextant, and eagerly pursued his favourite study: in the society of this amiable lady he lived happily for five-and-fifty years. In 1683 he published his Theory of the variation of the Magnetical Compass; in which he supposes the whole globe of the earth to be one great magnet, having four magnetical poles, or points of attraction, &c. The same year also he entered upon a new method of finding the longitude, by an accurate observation of the moon's motion. His pursuits it seems were now a little interrupted by the death of his father, who having suffered greatly by the fire of London, as well as by a second marriage, into which he had imprudently entered, was found to have wasted his fortune. Our author however soon resumed his pursuits; for in the beginning of 1684 he turned his thoughts to the subject of Kepler's sesqui-alterate proportion; when, after some meditation, he concluded from it, that the centripetal force must decrease in proportion to the square of the distance reciprocally. He found himself unable to make it out in any geometrical way, and therefore, after applying in vain for assistance to Dr. Hooke and Sir Christopher Wren, he went to Cambridge to Mr. Newton, who fully supplied him with what he so ardently sought. But Halley having now found an immense treasure in Newton, could not rest, till he had prevailed with the owner to enrich the public with it; and to this interview the world is in some measure indebted for the Principia Mathematica Philosophiae Naturalis. That great work was published in 1686; and Halley, who had the whole care of the impression, prefixed to it a discourse of his own, giving a general account of the astronomical part of the book; and also an elegant copy of verses in Latin.

In 1687 he undertook to explain the cause of a natural phenomenon, which had till then baffled the researches of the ablest geographers. It is observed that the Mediterranean sea never swells in the least, though there is no visible discharge of the prodigious quantity of water that runs into it from nine large rivers, besides several small ones, and the constant setting in of the current at the mouth of the Straits. His solution of this difficulty gave so much satisfaction to the R. Society, that he was requested to prosecute these enquiries. He did so; and having shown, by many accurate experiments, how that vast accession of water was actually carried off in vapours, raised by the action of the sun and wind upon its surface, he proceeded with the like success to point out the method used by nature to return the said vapours into the sea. This circulation he supposes to be carried on by the winds driving these vapours to the mountains; where being collected, they form springs, which uniting become rivulets or brooks, and many of these again meeting in the valleys, grow into large rivers, emptying themselves at

last into the sea : thus demonstrating, in the most beautiful and satisfactory manner, the way in which the equilibrium of receipt and expense is continually preserved in the universal ocean.

He next ranged in the field of speculative geometry, where, observing some imperfections in the methods before given for constructing solid problems, or equations of the 3d and 4th powers, he furnished new rules, which were both more easy and more elegant than any of the former; together with a new method of finding the number of roots of such equations, and the limits of the same. Mr. Halley next undertook to publish a more correct Ephemeris for the year 1688, there being then great want of proper ephemerides of any tolerable exactness, the common ones being justly complained of by Mr. Flamsteed.—In 1691 he published exact tables of the conjunctions of Venus and Mercury; and he afterwards showed one extraordinary use to be made of those tables, viz, for discovering the sun's parallax, and thence the true distance of the earth from the sun.—In 1692, our author produced his tables for showing the value of annuities on lives, calculated from bills of mortality; and his universal theorem for finding the foci of optic glasses.

But it would be endless to enumerate all his valuable discoveries now communicated to the Royal Society, and published in the Philos. Trans. of which, for many years, his pieces were the chief ornament and support. Their various merit is thrown into one view by the writer of his eulog in the Paris Memoirs; who, having mentioned his History of the Trade-winds and Monsoons, proceeds in these terms: “This was immediately followed by his estimation of the quantity of vapours which the sun raises from the sea; the circulation of vapours; the origin of fountains; questions on the nature of light and transparent bodies; a determination of the degrees of mortality, in order to adjust the valuation of annuities on lives; and many other works in the sciences, relating to astronomy, geometry, and algebra, optics and dioptrics, ballistics and artillery, speculative and experimental philosophy, natural history, antiquities, philology, and criticism; being about 25 or 30 dissertations, which he produced during the 9 or 10 years of his residence at London; and all abounding with ideas new, singular, and useful.”

In 1691, the Savilian professorship of astronomy at Oxford being vacant, he applied for that office, but without success. Whiston, in the Memoirs of his own Life, tells us from Dr. Bentley, that Halley “being thought of for successor to the mathematical chair at Oxford, bishop Stillingfleet was desired to recommend him at court; but hearing that he was a sceptic and a banterer of religion, the bishop scrupled to be concerned, till his chaplain Bentley should confer with him on the subject, which he did. But Halley was so sincere in his infidelity, that he would not so much as pretend to believe the Christian religion, though he was likely to lose a professorship: and it was in consequence given to Dr. David Gregory.”

Halley had published his Theory of the Variation of the Magnetical Compass, as has been already observed, in 1683; which, though it was well received both at home and abroad, he found, upon a review, liable to great and insuperable objections. Yet the phenomena of the variation of the needle, upon which it is raised, being so many certain and indisputable facts, he spared no pains to possess himself of all the observations relating to it he could possibly come at. To this end he procured an applica-

tion to be made to King William, who appointed him commander of the Paramour pink, with orders to search out by observations the discovery of the rule of variations, and to lay down the longitudes and latitudes of the English settlements in America.—He set out on this attempt on the 24th of November, 1698; but having crossed the line, his men grew sickly, and his first-lieutenant mutinying, he returned to England in June 1699. Having got the lieutenant tried and cashiered, he set sail a second time in September following, with the same ship, and another of less bulk, of which he had also the command. He now traversed the vast Atlantic ocean from one hemisphere to the other, as far as the ice would permit him to go; and having made his observations at St. Helena, Brazil, Cape Verde, Barbadoes, the Madeiras, the Canaries, the coast of Barbary, and many other latitudes, he arrived in England in September 1700; and the next year published a general chart, showing at one view the variation of the compass in all those places.

Captain Halley, as he was now called, had been at home little more than half a year, when he was sent by the king, to observe the course of the tides, with the longitude and latitude of the principal head-lands in the British channel; which having executed with his usual expedition and accuracy, he published a large map of the channel. Soon after, the Emperor of Germany resolving to make a convenient harbour for shipping in the Adriatic, Captain Halley was sent by Queen Anne to view the two ports on the coast of Dalmatia. He embarked on the 22d of November 1702; passed over to Holland; and going through Germany to Vienna, he proceeded to Istria; but the Dutch opposing the design, it was laid aside; yet the emperor made him a present of a rich diamond ring from his finger, and honoured him with a letter of recommendation, written with his own hand, to Queen Anne. It was not long after his return that he was sent again on the same business; when passing through Hanover, he supped with the Electoral Prince, who was afterwards King George the 1st, and his sister the queen of Prussia. On his arrival at Vienna, he had likewise the honour the same evening to be presented to the emperor, who sent his chief engineer to attend him to Istria, where they repaired the fortifications of Trieste, and added new ones.

Mr. Halley returned to England in November 1703; and the same year he was made professor of geometry in the university of Oxford, instead of Dr. Wallis, then just deceased. On his accession to this office the university was pleased to honour him with the degree of doctor of laws. He was scarcely settled in Oxford, when he began to translate into Latin, from the Arabic, Apollonius de Sectione Rationis; and to restore the two books De Sectione Spatii of the same author, which are lost, from the account given of them by Pappus; and he published the whole work in 1706. He afterwards had a share in preparing for the press Apollonius's Conics; and ventured to supply the whole 8th book, the original of which is also lost. To this work he added Screnus on the Section of the Cylinder and Cone, printed from the original Greek, with a Latin translation, and published the whole in folio 1710. Besides these, the Miscellanea Curiosa, in 3 volumes 8vo, had come out under his direction in 1708.

In 1713, he succeeded Doctor, afterwards Sir, Hans Sloane, in the office of secretary to the Royal Society. And, on the death of Mr. Flamsteed in 1719, he was appointed to succeed him at Greenwich as astronomer-royal;

on which occasion, that he might be more at leisure to attend the duties of this important situation, he resigned the office of secretary to the Royal Society in 1721. Though he was 63 or 64 years of age when he entered on his office at Greenwich, yet for the space of 18 years he watched the heavens with the closest attention, hardly ever missing an observation during all that time, and, without any assistant, performed the whole business of the observatory himself.

On the accession of the late king, the queen consort Caroline made a visit to the Royal Observatory: being pleased with every thing she saw, and understanding the smallness of the astronomer's salary (100*l.* a year), her majesty very graciously said that she would speak to the king to have it increased; to which Dr. Halley, alarmed, replied, "Pray your majesty do no such thing; for should the salary be increased, it might become an object of emolument to place there some unqualified needy dependent, to the ruin of the institution." However, understanding that the Dr. had formerly served the crown as a captain in the navy, she soon after obtained a grant of his half-pay for that commission, which he accordingly enjoyed from that time during his life. An offer was also made him of being appointed mathematical preceptor to the Duke of Cumberland; but he declined that honour, on account of his advanced age, and the duties of his office. In 1729 he was chosen a foreign member of the Academy of Sciences at Paris.

About 1737 he was seized with a paralytic disorder in his right hand, which, it is said, was the first attack he ever felt on his constitution: however, he came as usual, once a week, till within a very short time of his death, to meet his friends in town on Thursdays, the day of the Royal Society's meeting, at what is still called Dr. Halley's club. His paralytical disorder increasing, his strength gradually wore away, till he expired Jan. 14, 1742, in the 86th year of his age; and his corps was interred in the church-yard of Lee near Blackheath.

Besides the works before mentioned, his principal publications are, 1. Catalogus Stellarum Australium. 2. Tabula Astronomicae. 3. The Astronomy of Comets. With a great multitude of papers in the Philos. Trans. from vol. 11 to vol. 60.

HALIFAX (JON.). See HOLYWOOD.

HALO, or CORONA, a coloured circle appearing round the body of the sun, moon, or the larger stars.

Naturalists conceive the halo to arise from a refraction of the rays of light, in passing through the fine rarc vesiculae of thin vapour, towards the top of the atmosphere.

Descartes observes, that the halo never appears when it rains; whence he concludes that this phenomenon is occasioned by the refraction of light in the round particles of ice, which are then floating in the atmosphere; and to the different protuberance of these particles he ascribes the variation in the diameter of the halo. Gassendi supposes, that a halo is occasioned in the same manner as the rainbow; the rays of light being, in both cases, twice refracted and once reflected within each drop of rain or vapour, and that the difference between them arises entirely from their different situation with respect to the observer. Dechales also endeavoured to show that the generation of the halo is similar to that of the rainbow; and that the reason why the colours of the halo are more dilute than those of the rainbow, is owing chiefly to their being formed, not in large drops of rain, but in very small vapour.

But the most considerable and generally received theory, relating to the generation of halos, is that of Huygens. This celebrated author supposes halos, or circles round the sun, to be formed by small round grains of hail, composed of two different parts, the one of which is transparent, inclosing the other, which is opaque: And this is the general structure actually observed in hail. He further supposes that the grains or globules, that form these halos, consisted at first of soft snow, and that they have been rounded by a continual agitation in the air, and thawed on their outside by the heat of the sun, &c. And he illustrates his ideas of their formation by geometrical figures.

Mr. Weidler endeavours to refute Huygens's manner of accounting for halos, by a vast number of small vapours, each with a snowy nucleus, coated round with a transparent covering. He observes, that when the sun paints its image in the atmosphere, and by the force of its rays puts the vapours in motion, and drives them toward the surface, till they are collected in such a quantity, and at such a distance from the sun on each side, that its rays are twice refracted, and twice reflected, they will when they reach the eye exhibit the appearance of a halo, adorned with the colours of the rainbow; which may happen in globular pellucid vapours without snowy nuclei, as appears by the experiment of hollow glass spheres filled with water: therefore, whenever those spherical vapours are situated as before mentioned, the refractions and reflections will happen every where alike, and the figure of a circular crown, with the usual order of colours, will be the consequence. Philos. Trans. No. 458.

Newton's theory of halos may be seen in his Optics, pa. 155. And this curious theory was confirmed by actual observation in June 1692, when the author saw by reflection, in a vessel of stagnated water, three halos, crowns, or rings of colours, about the sun, like three small rainbows concentric to his body. These crowns inclosed one another immediately, so that their colours proceeded in this continual order from the sun outward : blue, white, red; purple, blue, green, pale yellow, and red; pale blue, pale red. Crowns like these sometimes appear about the moon. The more equal the globules of water or ice are to one another, the more crowns of colours will appear, and the colours will be the more lively. Optics, pa. 288.

There are several ways of exhibiting phenomena similar to these. The flame of a candle, placed in the midst of a steam in cold weather, or set at the distance of some feet from a glass window that has been breathed upon, while the spectator is also at the distance of some feet from another part of the window, or placed behind a glass receiver, when air is admitted into the vacuum within it to a certain density, in each of these circumstances will appear to be encompassed by a coloured halo. Also, a quantity of water being thrown up against the sun, will, as it breaks and disperses into drops, form a kind of halo or iris, exhibiting all the colours of the natural rainbow. Muschenbroek observed, that when the glass windows of his room were covered with a thin plate of ice on the inside, the moon seen through it was surrounded with a large and variously coloured halo; which, upon opening the window, he found arose entirely from that thin plate of ice, because none was observed except through this plate. The same author concludes his account of coronas with observing, that some density of vapour, or some thickness of the plates of ice, divides the light in its transmission

either through the small globules or their interstices, into its separate colours; but what that density is, or what the size of the particles which compose the vapour may be, he does not pretend to determine. *Introd. ad Phil. Nat.* pa. 1037.

It has often been observed that a halo about the sun or moon, does not appear circular and concentric to the luminary, but oval and eccentric, with its longest diameter perpendicular to the horizon, and extended from the moon farther downward than upward. Dr. Smith ascribes this phenomenon to the apparent concave vault of the sky being less than a hemisphere. When the angle which the diameter of a halo subtends at the eye is 45° or 46° , and the bottom of the halo is near the horizon, and consequently its apparent figure is most oval, the apparent vertical diameter is divided by the moon in the proportion of about 2 to 3 or 4, and is to the horizontal diameter drawn through the moon, as 4 to 3, nearly.—See farther on the subject of this article, Priestley's *Hist. of Discoveries relating to Vision*, pa. 596—613; and Smith's *Optics*, art. 167, 513, 526, 527, &c.

HAMEL (JOHN-BAPTISTE DU), a very learned French philosopher and writer, of the 17th century, was born in Lower Normandy in 1614. At 18 years of age he published a treatise, in which he explained, in a very simple manner, and by one or two figures, Theodosius's 3 books on Spherics; to which he added a tract on trigonometry extremely perspicuous, and designed as an introduction to astronomy. He published afterwards various other works on astronomy and philosophy. Natural philosophy, as it was then taught, was only a collection of vague, knotty, and barren questions; when our author undertook to establish it upon right principles, and published his *Astronomia Physica*.

In 1666 M. Colbert proposed to Louis the 14th a scheme, which was approved of, for establishing a royal academy of sciences; and appointed our author secretary of it. In 1678, his *Philosophia Vetus et Nova* was printed at Paris in 4 vols, 12mo; and in 1681 it was enlarged and printed there in 6 vols. Hamel wrote several other pieces; and his works in this way were collected and published at Nuremberg 1681, in 4 volumes 4to, under the title of *Opera Philosophica et Astronomica*. These were highly valued at that period, though the improvements in philosophy since that time have rendered them of little or no use in the present.

In 1697, our author resigned his place of secretary of the Royal Academy of Sciences; in which he was succeeded by M. Fontenelle. However, he published, in 1698, *Regia Scientiarum Academæ Historia*, 4to, in four books; which being much approved, he afterwards augmented with two books more. This work contains an account of the foundation of the Royal Academy of Sciences, and its transactions, from 1660 to 1700, and is now the most useful of all his works. He was Regius Professor of Philosophy, in which office he was succeeded by M. Varignon, at his death, which happened Aug. 6, 1706, in the 93d year of his age.

HAMILTON (Dr. HUGH), a very respectable mathematician, and philosopher, was born at Knock, in the county of Dublin, March 26, 1720. He entered Trinity-college, Dublin, in November 1742, and obtained a fellowship in that college in 1751, when he was only 22 years of age. In the year 1758, he published his well-known and much-admired *Treatise on Conic Sections*;

and the next year was elected Erasmus Smith's professor of natural philosophy. In the discharge of his duty as professor, he composed and published four lectures introductory to the study of natural philosophy: and in the year 1762, he wrote three philosophical essays on the ascent of vapours, the formation of clouds, rain, &c; on the nature of the aurora borealis, and the tails of comets; and on the principles of mechanics.

Dr. Hamilton resigned his fellowship in 1764, having accepted the living of Kilmacrenan, in the gift of the college: in 1767, he was collated to the parish of St. Anne's, Dublin. This latter preferment was soon exchanged for the deanship of Armagh. In 1772, he married; and soon after published his essay on the existence and attributes of the Supreme Being. In the year 1792, he made some important improvements in the construction of the barometer; and in 1794, drew up a paper on the power of fixed caustic alkaline salts, to preserve the flesh of animals from putrefaction. All this time he continued to attend sedulously and conscientiously to his duties as a parish priest. In January 1796, he was consecrated bishop of Clonfert; and about 3 years afterwards he was translated to the see of Ossory, of which he continued bishop nearly seven years. He died Dec. 1, 1805, in the 77th year of his age.

The principal trait in the disposition of Bishop Hamilton, was unaffected humility: his chief intellectual characteristic, a patient manner of thinking. His theory of the solution of water in air is now exploded, and his theory of the aurora borealis has yielded to that of M. Libes. (See Aurora Borealis). But his mechanical essays may still be read with pleasure and advantage. Dr. Hamilton's works have been lately collected and published by his son Alexander Hamilton, in 2 vols. 8vo; of which, the first contains the Latin edition of the *Conic Sections*.

HANCES, **HANCHES**, or **HANSES**, in Architecture, are certain intermediate parts of arches between the key or crown and the spring at the bottom, being perhaps about one-third of the arch, and situated nearer the bottom than the top or crown; and are otherwise called the spandrels.

HANDSPIKE, or **HANSPEC**, a lever or piece of ash, elm, or other strong wood, for raising by the hand great weights, &c. It is 5 or 6 feet long, cut thin and crooked at the lower end, that it may be forced more readily between things required to be separated, or under any thing that is to be raised. It is better than a crow of iron, because its length allows a better poise.

HARD Bodies, are such as are absolutely inflexible to any pressure or percussion whatever: differing from soft bodies, whose parts yield and are easily moved among one another, without restoring themselves again; and from elastic bodies, the parts of which also yield and give way, but presently restore themselves again to their former state and situation. Hence, hard bodies do not bend, or indent, but break. It is probable however there are no bodies in nature that are absolutely or perfectly either hard, soft, or elastic; but all possessing these qualities, more or less, in some degree. M. Bernoulli asserts that hardness, in the common sense, is absolutely impossible, being contrary to the law of continuity. The laws of motion for hard bodies are the same as for soft ones, both being supposed to adhere together on their impact. And these two kinds of bodies might be comprised under the common name of Un-elastic.

HARDENING, the giving a greater degree of hardness to bodies than they had before. There are several ways

of hardening iron and steel; as by hammering them, quenching them in cold water, &c.

Case-HARDENING, is a superficial conversion of iron into steel, as if it were casing it, or covering it with a thin coat of harder matter. It is thus performed: Take cow-horn or hoof, well-dried in an oven, and beat it to powder; put equal quantities of this powder and of bay-salt into stale urine, or white-wine vinegar, and mix them well together; cover the iron or steel with this mixture, and wrap it up in loam, or plate iron, so as the mixture may touch every part of the work; then put it in the fire, and blow the coals, till the whole lump has acquired a blood-red heat, but no higher; lastly, take it out, and quench it.—See **STEEL**, under which article are described other processes for this purpose.

HARDING, a small new primary planet, called also **Juno**, discovered by the astronomer M. Harding.

HARDNESS, or **RIGIDITY**, that quality in bodies by which their parts so cohere as not to yield inward, or give way to an external impulse, without instantly going beyond the distance of their mutual attraction; and therefore are not subject to any motion in respect of each other, without breaking the body. There were many fanciful opinions among the ancients, concerning the cause of hardness; such as heat, cold, dryness, the hooked figure of the particles of matter. The Cartesians make the hardness of bodies to consist in rest, as that of soft and fluid ones in the motion of their particles.

Newton shows that the primary particles of all bodies, whether solid or fluid, are perfectly hard; and are not capable of being broken or divided by any power in nature. These particles, he maintains, are connected and kept together by an attractive power; and according to the circumstances of this attraction, the body is either hard, or soft, or even fluid. If the particulars be so disposed or fitted for each other, as to touch in large surfaces, the body will be hard; and the more so as those surfaces are the larger. If, on the contrary, they only touch in small surfaces, the body, by the weakness of the attraction, will remain soft. At present, many philosophers are of opinion, that hardness consists in the absence or want of the action of the universal fluid, or elementary fire, among the particles of the body, or a deficiency of what is called latent heat; while on the contrary, fluidity, according to them, consists in the motion of the particles, in consequence of the action of that elementary fire.

Hardness appears to diminish the cohesion of bodies, in some degree, though their frangibility or brittleness does not by any means keep pace with their hardness. Thus, though glass be very hard and very brittle; yet flint is still harder, though less brittle. Among the metals, these two properties seem to be more connected, though even here the connexion is by no means complete: for though steel be both the hardest and most brittle of all the metals; yet lead, which is the softest, is not the most ductile. Neither is hardness connected with the specific gravity of bodies; for a diamond, the hardest substance in nature, is little more than half the weight of the lightest metal. And as little is it connected with the coldness, or electrical properties, or any other quality with which we are acquainted. Some bodies are rendered hard by cold, and others by different degrees of heat.

Mr. Quist and others have constructed tables of the hardness of different substances. And the manner of constructing these tables, was by observing the order in which

they were able to cut or make any impression upon one another. The following table, extracted from Magellan's edition of Cronstedt's *Mineralogy*, was taken from Quist, Bergman, and Kirwan. The first column shows the hardness, and the second the specific gravity.

	Hard- ness.	Spec. Grav.
Diamond from Ormus	20	3·7
Pink diamond	19	3·4
Blueish diamond	19	3·3
Yellowish diamond	19	3·3
Cubic diamond	18	3·2
Ruby	17	4·2
Pale blue sapphire	17	3·8
Pale ruby from Brazil	16	3·5
Deep blue sapphire	16	3·8
Topaz	15	4·2
Whitish ditto	14	3·5
Ruby spinell	13	3·4
Emerald	12	2·8
Garnet	12	4·4
Agate	12	2·6
Onyx	12	2·6
Sardonyx	12	2·6
Bohemian topaz	11	2·8
Occid. amethyst	11	2·7
Crystal	11	2·6
Carnelian	11	2·7
Green jasper	11	2·7
Schoerl	10	3·6
Tourmaline	10	3·0
Quartz	10	2·7
Opal	10	2·6
Chrysolite	10	3·7
Reddish yellow jasper	9	2·6
Zoelyte	8	2·1
Fluor	7	3·5
Calcareous spar	6	2·7
Gypsum	5	2·3
Chalk	3	2·7

HARMONICA, **HARMONICS**, a branch or division of the ancient music; being that part which considers the differences and proportions of sounds, with respect to acute and grave; as distinguished from rhythmic, and metrical. Mr. Malcolm has made a very industrious and learned inquiry into the Harmonica, or harmonic principles of the ancients.

HARMONICA, the name of a musical instrument invented by Dr. Franklin, consisting of the glasses, called musical glasses.—We are informed that the first hint of musical glasses is to be found in an old English book, in which a number of various amusements were described. That author directs his pupil to choose half a dozen drinking-glasses; to fill each of them with water in proportion to the gravity or acuteness of the sound which it is intended to give; and having thus adjusted them to each other, he might entertain the company with a church tune. These were perhaps the rude hints which Mr. Puckridge, an Irish gentleman, afterwards improved, and after him, Mr. E. Delaval, an ingenious member of the Royal Society; and finally brought to perfection by the celebrated Franklin. See the history and description in his Letters, particularly in that to Beccaria.

HARMONICAL, or **HARMONIC**, something relating to Harmony. Thus,

HARMONICAL Arithmetic, is so much of the theory and doctrine of numbers, as relates to making the comparisons and reductions of musical intervals, which are expressed by numbers, for finding their mutual relations, compositions, and resolutions.

HARMONICAL Composition, in its general sense, includes the composition both of harmony and melody; i. e. of music, or song, both in a single part, and in several parts.

HARMONICAL Interval, the difference between two sounds, in respect of grave and acute: or that imaginary space terminated with two sounds differing in acuteness or gravity.

HARMONICAL CURVE, an imaginary kind of curve, into which it has been supposed that a musical chord would be inflected when put into such a vibratory motion as excited sound. It has been asserted by Dr. Brook Taylor, and others, that if a chord be inflected into any other form than that of the harmonic curve, it will, since those parts which are without this figure are impelled towards it, by an excess of force, and those within it by a deficiency, in a very short time arrive at, or very near, the form of this precise curve. But, as Dr. T. Young very properly remarks, "it would be easy to prove, if this reasoning were allowed, that the form of the curve can be no other than that of the axis, since the tending force is continually impelling the chord towards this line." Philos. Trans. 1800, pt. 1.—In theory, a musical chord is conceived to be a mathematical line, flexible by the least force, and elastic: and when such chord, at the limit of its vibration, assumes the form of this harmonic curve, it will vibrate to and fro in curves of the same species.—According to the investigation of Dr. Smith, the figure contained under the harmonical curve and its base, is of the same species as the figure of sines. From the investigation it follows: 1. That the force by which any small particle of an elastic string is impelled towards the centre of its curvature, is to the tending force, as the length of the particle, is to the radius of curvature. 2. The perpendicular distance of a particle from the string in its quiescent position, is to the string's length, as the same length, is to the radius of curvature in the square of $3\cdot14159$. Hence, if any perpendicular distance d be put = d , the string's length = s , and $3\cdot14159 = c$, then will the radius of curvature $d = \frac{ss}{dc^2}$. 3. Each particle of the string will arrive at the axis at the same instant of time. But it is all along supposed that the greatest distance of the string from the axis, bears no sensible proportion to its length. See Smith's Harmon. pa. 248, &c; also Notes to the Jesuits' Newton, tom. 2, pa. 348.

HARMONICAL Proportion, or **Musical Proportion**, is that in which the first term is to the third, as the difference of the first and second is to the difference of the 2d and 3d; or when the first, the third, and the said two differences, are in geometrical proportion. Or, four terms are in harmonical proportion, when the 1st is to the 4th, as the difference of the 1st and 2d is to the difference of the 3d and 4th. Thus, 2, 3, 6, are in harmonical proportion, because $2:6::1:3$. And the four terms 9, 12, 16, 24 are in harmonical proportion, because $9:24::3:8$.—If the proportional terms be continued in the former case, they will form an harmonical progression, or series.

1. The reciprocals of an arithmetical progression are in harmonical progression; and, conversely, the reciprocals of harmonicals are arithmeticals. Thus, the reciprocals

of the harmonicals 2, 3, 6, are $\frac{1}{2}, \frac{1}{3}, \frac{1}{6}$, which are arithmeticals; for $\frac{1}{2} - \frac{1}{3} = \frac{1}{6}$, and $\frac{1}{3} - \frac{1}{6} = \frac{1}{6}$; also: and the reciprocals of the arithmeticals 1, 2, 3, 4, &c., are $\frac{1}{1}, \frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \&c.$, which are harmonicals; for $\frac{1}{1} : \frac{1}{2} :: \frac{1}{1} - \frac{1}{2} : \frac{1}{2} - \frac{1}{3}$; and so on. And, in general, the reciprocals of the arithmeticals $a, a+d, a+2d, a+3d, \&c.$, viz,

$\frac{1}{a}, \frac{1}{a+d}, \frac{1}{a+2d}, \frac{1}{a+3d}, \&c.$, are harmonicals; et c. contra.

2. If three or four numbers in harmonical proportion be either multiplied or divided by some number, the products, or the quotients, will still be in harmonical proportion. Thus,

the harmonicals	-	6, 8, 12,
multiplied by 2 give	-	12, 16, 24,
or divided by 2 give	-	3, 4, 6,

which are also harmonicals.

3. To find a harmonical mean proportional between two terms: divide double their product by their sum.

4. To find a 3d term in harmonical proportion to two given terms: divide their product by the difference between double the 1st term and the 2d term.

5. To find a 4th term in harmonical proportion to three terms given; divide the product of the 1st and 3d by the difference between double the 1st and the 2d term.

Hence, of the two terms 6 and 3,
the harmonical mean is 4,
the 3d harmonical proportion is 2,
also to 6, 4, 3, the 4th harmonical is 2.

6. If there be taken an arithmetical mean, and a harmonical mean, between any two terms, the four terms will be in geometrical proportion. Thus, between 6 and 2,
the arithmetical mean is 4, and
the harmonical mean is 3;
and hence $6:4::3:2$.

7. Also the arithmetical mean, the geometrical mean, and the harmonical mean, between any two terms, are three terms in continued geometrical progression. So, between 6 and 2, the arithmetical mean is 4, the geometrical mean is $\sqrt{12}$, and the harmonical mean is 3; then $4:\sqrt{12}::\sqrt{12}:3$.

HARMONY, in Music, the agreeable result of an union of several musical sounds, heard at one and the same time; or the mixture of divers sounds, which together have an agreeable effect on the ear.—As a continued succession of musical sounds produces melody, so a continued combination of them produces harmony. Among the ancients, however, as sometimes also among the moderns, harmony is used in the strict sense of consonance; and so is equivalent to the symphony.

The words concord and harmony do really signify the same thing; though custom has made a little difference between them. Concord is the agreeable effect of two sounds in consonance; harmony the effect of any greater number of agreeable sounds in consonance. Again, harmony always implies consonance; but concord is also applied to sounds in succession; though never but where the terms can stand agreeably in consonance. The effect of an agreeable succession of several sounds, is called melody; as that of an agreeable consonance is called harmony.

Harmony is well defined, the sum or result of the combination of two or more concords; that is, of three or more simple sounds striking the ear altogether; and different compositions of concords constitute various degrees of harmony. The ancients seem to have been entirely un-

acquainted with harmony, the soul of the modern music. In all their explications of the melopeia, they say not one word of the concert or harmony of parts. We have instances, indeed, of their joining several voices, or instruments, in consonance; but then these were not so joined, as that each had a distinct and proper melody, so making a succession of various concords; but they were either unisons, or octaves, in every note; and so all performed the same individual melody, and constituted one song. When the parts differ, not in the tension of the whole, but in the different relations of the successive notes, it is this that constitutes the modern art of harmony.

HARMONY of the Spheres, or Celestial Harmony, a kind of music much spoken of by many of the ancient philosophers and fathers, supposed to be produced by the sweetly tuned motions of the stars and planets. This harmony they attributed to the various proportionate impressions of the heavenly bodies on one another, acting at proper intervals. They think it impossible that such prodigious bodies, moving with such rapidity, should be silent: on the contrary, the atmosphere, continually impelled by them, must yield a set of sounds proportionate to the impression it receives; and that consequently, as they run all in different circuits, and with various degrees of velocity, the different tones arising from the diversity of motions, directed by the hand of the Almighty, must form an agreeable symphony or concert. They therefore supposed, that the moon, as being the lowest of the planets, corresponded to *mi*; Mercury, to *fa*; Venus, to *sol*; the Sun, to *la*; Mars, to *si*; Jupiter, to *ut*; Saturn, to *re*; and the orb of the fixed stars, as being the highest of all, to *mi*, or the octave.

It is thought that Pythagoras had a view to the gravitation of celestial bodies, in what he taught concerning the harmony of the spheres. A musical chord gives the same note as one double in length, when the tension or force with which the latter is stretched is quadruple; and the gravity of a planet is quadruple of the gravity of a planet at a double distance. In general, that any musical chord may become unison to a lesser chord of the same kind, its tension must be increased in the same proportion as the square of its length is greater; and that the gravity of a planet may become equal to the gravity of another planet nearer the sun, it must be increased in proportion as the square of its distance from the sun is greater. If therefore we should suppose musical chords extended from the sun to each planet, that all these chords might become unison, it would be requisite to increase or diminish their tensions in the same proportions as would be sufficient to render the gravities of the planets equal; and from the similitude of those proportions, the celebrated doctrine of the harmony of the spheres is supposed to have been derived.

Kepler wrote a large work, in folio, on the harmonies of the world, and particularly of that of the celestial bodies. He first endeavoured to find out some relation between the dimensions of the five regular solids, and the intervals of the planetary spheres; and imagining that a cube, inscribed in the sphere of Saturn, would touch by its six planes the sphere of Jupiter, and that the other four regular solids in like manner fitted the intervals that are between the spheres of the other planets, he became persuaded that this was the true reason why the primary planets were precisely six in number, and that the author of the world had determined their distances from the sun,

the centre of the system, from a regard to this analogy. But afterwards finding that the disposition of the five regular solids among the planetary spheres, was not agreeable to the intervals between their orbits, he endeavoured to discover other schemes of harmony. For this purpose, he compared the motions of the same planet at its greatest and least distances, and of the different planets in their several orbits, as they would appear viewed from the sun; and here he fancied that he found a similitude to the divisions of the octave in music. Lastly, he imagined that if lines were drawn from the earth, to each of the planets, and the planets appended to them, or stretched by weights proportional to the planets, these lines would then sound all the notes in the octave of a musical chord. See his Harmonics; also Plin. lib. 2, cap. 22; Macrob. in Somn. Scip. lib. 2, cap 1; Plutarch. de Animal. Procreatio, & Timao; and Maclaurin's View of Newton's Discov. book 1, chap. 2.

HARQUEBUSS, a hand-gun, or a fire-arm of a proper length and weight to be borne in the arm. Hanzel pre-scribes its proper length to be 40 calibres, or diameters of its bore; and the weight of its ball 1 oz. and $\frac{1}{2}$; its charge of powder as much.

HARRIOT (THOMAS), a very eminent English mathematician and astronomer, was born at Oxford in 1560, and died at London July 2, 1621, in the 61st year of his age. Harriot has hitherto been known to the world only as an algebraist, though a very eminent one; but from his manuscript papers, that have been but lately discovered by Dr. Zach, astronomer to the duke of Saxe-Gotha, it appears that he was not less eminent as an astronomer and geometrician. Dr. Zach has printed an account of those papers, in the Astronomical Ephemeris of the Royal Academy of Sciences at Berlin, for the year 1788; of which, as it is very curious, and contains a great deal of information, I shall here give a translation, to serve as memoirs concerning the life and writings of this eminent man; afterwards adding only some necessary remarks of my own.

"I here present to the world," says Dr. Zach, "a short account of some valuable and curious manuscripts, which I found in the year 1784, at the seat of the earl of Egremont, at Petworth in Sussex, in hopes that this learned and inquisitive age will either think my endeavours about them worthy of its assistance, or else will be thereby induced to attempt some other means of publishing them. The only undeniable proof I can now produce, of the usefulness of such an undertaking, is by giving a succinct report of the contents of these materials, and briefly showing what may be effected by them. And though I come to the performance of such an enterprise with much less abilities than the different parts of it require, yet I trust that my love for truth, my design and zeal to vindicate the honour due to an Englishman, the author of these manuscripts, which are the chief reasons that have influenced me in this undertaking, will serve as my excuse."

"A predecessor of the family of Lord Egremont, viz., that noble and generous earl of Northumberland, named Henry Percy, was not only a generous favourite of all good learning, but also a patron and Mæcenas of the literati of his age. Thomas Harriot, the author of the said manuscripts, Robert Hues (well known by his Treatise upon the Globes), and Walter Warner, all three eminent mathematicians, who were known to the earl, received from him yearly pensions; so that when the earl was committed pri-

somer to the Tower of London in the year 1606, our author, with Hues and Warner, were his constant companions; and were usually called the earl of Northumberland's three Magi.

" Thomas Harriot is a known and celebrated mathematician among the learned of all nations, by his excellent work, *Artis Analyticae Praxis, ad aquationes algebraicas nova expedita et generali methodo, resolvendas, Tractatus posthumus*; Lond. 1631: dedicated to Henry earl of Northumberland; published after his death by Walter Warner. It is remarkable, that the fame and the honour of this truly-great man were constantly attacked by the French mathematicians; who could not endure that Harriot should in any way diminish the fame of their Vieta and Descartes, especially the latter, who was openly accused of plagiarism from our author. [See Montucla's *Histoire des Mathématiques*, part 3, pa. 485 et seq.—*Lettres de M. Descartes*, tom. 3, pa. 457, edit. Paris 1667, in 4to.—*Dictionnaire de Morrieri*, word *Harriot*.—*Encyclopedie*, word *Algebra*.—*Lettres de M. de Voltaire, sur la nation Angloise*, lettre 14.—*Mémoire de l'Abbé de Gua dans les Mem. de l'Acad. des Sciences de Paris pour 1741*.—*Jer. Collier's great Historical Dictionary*, word *Harriot*.—Dr. Wallis's preface to his *Algebra*.—To which may be added the article *Algebra*, in this dictionary.]

" Descartes published his Geometry 6 years after Harriot's work appeared, viz., in the year 1637. Sir Charles Cavendish, then ambassador at the French court at Paris, when Descartes's Geometry made its first appearance in public, observed to the famous geometrician Roberval, that these improvements in analysis had been already made these 6 years in England, and showed him afterwards Harriot's *Artis Analyticae Praxis*; which, as Roberval was looking over, at every page he cried out, *Oui! oui! il l'a vu! Yes! yes! he has seen it!* Descartes had also been in England before Harriot's death, and had heard of his new improvements and inventions in analysis. A critical life of this man, which his papers would enable me to publish, will show more clearly what to think upon this matter, which I hope may be discussed to the due honour of our author.

" Now all this relates to Harriot the celebrated analyst; but it has not hitherto been known that Harriot was an eminent astronomer, both theoretical and practical, which first appears by these manuscripts; among which the most remarkable are 199 observations of the Sun's Spots, with their drawings, calculations, and determinations of the sun's rotation about his axis. There is the greatest probability that Harriot was the first discoverer of these spots, even before either Galileo or Scheiner. The earliest intelligence we have of the first discovered solar spots, is of one Joh. Fabricius Phrysius, who in the year 1611 published at Wittemberg a small treatise, intitled, *De Maculis in Sole observatis et apparente eorum cum Sole conversione narratio*. Galileo, who is commonly accounted the first discoverer of the solar spots, published his book, *Istoria e Dimonstrazioni intorno alle Macchie Solare e loro accidenti*, at Rome, in the year 1613. His first observation in this work, is dated June 2, 1612. Angelo de Filis, the editor of Galileo's work, who wrote the dedication and preface to it, mentions, pa. 3, that Galileo had not only discovered these spots in the month of April in the year 1611, at Rome, in the Quirinal Garden, but had shown them several months before (molti mesi innanzi) to his friends in Florence; and that the obser-

vations of the disguised Apelles (the Jesuit Scheiner, a pretender to this first discovery) were not later than the month of October in the same year; by which the epoch of this discovery was fixed to the beginning of the year 1611. But a passage in the first letter of Galileo's works, pa. 11, gives a more precise term to this discovery. Galileo there says in plain terms, that he had observed the spots in the sun 18 months before. The date of this letter is May 24, 1612; which brings the true epoch of this discovery to the month of November, 1610. However, Galileo's first produced observations are only from June 2, 1612, and those of Father Scheiner of the month of October, in the same year. But now it appears from Harriot's manuscripts, that his first observations of these spots are of Dec. 8, 1610. It is not likely that Harriot could have this notice from Galileo, for I do not find this mathematician's name ever quoted in Harriot's papers. But I find him mentioning Josephus a Costa's book 1, chap. 2, of his *Natural and Moral History of the West Indies*, in which he relates that in Peru there are spots to be seen in the sun which are not to be seen in Europe. It rather seems that Harriot had taken the hint from thence. Besides, it is very likely that Harriot, who lived with so generous a patron to all good learning and improvements, had got the new invention of telescopes in Holland much sooner in England, than they could reach Galileo, who at that time lived at Venice. Harriot's very careful and exact observations of these spots, show also that he was in possession of the best and most improved telescopes of that time; for it appears he had some with magnifying powers of 10, 20, and 30 times. At least there are no earlier observations of the solar spots extant than his: they run from December 8, 1610, till January 18, 1613. I compared the corresponding ones with these observed by Galileo, between which I found an exact agreement. Had Harriot had any notion about Galileo's discoveries, he certainly would have also known something about the phases of Venus and Mercury, and especially about the singular shape of Saturn, first discovered by Galileo; but I find not a word in all his papers concerning the particular figure of that planet.

" *Of Jupiter's Satellites.* I found among his papers a large set of observations, with their drawing, position, and calculations of their revolutions and periods. His first observation of those discovered satellites, I find to be of January 16, 1610; and they go till February 26, 1612. Galileo pretends to have discovered them January 7, 1610; so that it is not improbable that Harriot was likewise the first discoverer of these attendants of Jupiter.

" Among his other observations of the moon, of some eclipses, of the planet Mars, of solstices, of refraction, of the declination of the needle; there are most remarkable ones of the noted comets of 1607, and of 1618, the latter, for there were two this year (see Kepler de Cometis, pa. 49). They were all observed with a cross-staff, by measuring their distances from fixed stars; whence these observations are the more valuable, as comets had before been but loosely attended to: Kepler himself observed the comet of 1607 only with the naked eye, pointing out its place by a rough estimation, without the aid of an instrument; and the elements of their orbits could, in defect of better observations, be only calculated by them. The observations of the comet of the year 1607, are of the more importance, even now for modern astronomy, as

this is the same comet that fulfilled Dr. Halley's prediction of its return in the year 1759. That prediction was only grounded on the elements afforded him by these loose observations; for which reason he only assigned the term of its return to the space of a year. The very intricate calculations of the perturbations of this comet, afterwards made by M. Clairaut, reduced the limits to a month's space. But a greater light may now be thrown upon this matter by the more accurate observations on this comet by Mr. Harriot. In the month of October 1785, when I conversed on the subject of Harriot's papers, and especially on this comet, with the very celebrated mathematician M. Lagrange, director of the Royal Academy of Sciences at Berlin, he then suggested to me an idea, which, if brought into execution, will clear up an important point in astronomy. It is well known to astronomers how difficult a matter it is, to determine the mass, or quantity of matter, in the planet Saturn; and how little satisfactory the notions of it are, that have hitherto been formed. The whole theory of the perturbations of comets depending on this uncertain datum, several attempts and trials have been made towards a more exact determination of it by the most eminent geometers of this age, and particularly by Lagrange himself; but never having been satisfied with the few and uncertain data heretofore obtained for the resolution of this problem, he thought that Harriot's observations on the comet of 1607, and the modern ones of the same comet in 1759, would suggest a way of resolving the problem a posteriori; that of determining by them the elements of its ellipsis. The retardation of the comet compared to its period, may clearly be laid to the account of the attraction and perturbation it has suffered in the region of Jupiter and Saturn; and as the part of it belonging to Jupiter is very well known, the remainder must be the share which is due to Saturn; from whence the mass of the latter may be inferred. In consequence of this consideration I have already begun to reduce most of Harriot's observations of this comet, in order to calculate by them the true elements of its orbit on an elliptical hypothesis, to complete M. Lagrange's idea upon this matter.

"I forbear to mention here any more of Harriot's analytical papers, which I found in a very great number. They contain several elegant solutions of quadratic, cubic, and biquadratic equations; with some other solutions and loca geometrica, that show his eminent qualifications, and will serve to vindicate them against the attacks of several French writers, who refuse him the justice due to his skill and accomplishments, merely to save Descartes's honour, who yet, by some impartial men of his own nation, was accused of public plagiarism.

"Thomas Harriot was born at Oxford, in the year 1560. After being instructed in the rudiments of languages, he became a commoner of St. Mary's-Hall, where he took the degree of bachelor of arts in 1579. He had then so distinguished himself by his uncommon skill in mathematics, as to be recommended soon after to Sir Walter Raleigh, as a proper preceptor to him in that science. Accordingly that noble knight became his first patron, took him into his family, and allowed him a handsome pension. In 1584 he went over with Sir Walter's first colony to Virginia; where he was employed in discovering and surveying the country, &c; maps of which I have found (says Dr. Zach) very neatly executed among his papers. After his return he published A Brief and

True Report of the Newfoundland of Virginia, of the Commodities there found to be raised, &c; Lond. 1588. This was reprinted in the 3d volume of Hakluyt's Voyages: it was also translated into Latin, and printed at Frankfort in the year 1590. Sir Walter introduced him to the acquaintance of the Earl of Northumberland, who allowed him a yearly pension; Wood says, of 120*l.* only; but by some of his receipts, which I have found among his papers, it appears that he had 300*l.* which indeed was a very large sum at that time. Wood, in his Athen. Oxon. mentions nothing of Harriot's papers, except a manuscript in the library at Sion College, London, entitled Ephemeris Chymometrica. I got access to this library and manuscripts, and was indeed in hopes of finding something more of Harriot's; for most of his observations are dated from Sion College; but I could not find any thing from Harriot himself. I found indeed some other papers of his friends: he mentions, in his observations, one Mr. Standish, at Oxford, and Nathaniel Torperly, who also was of the acquaintance of the Earl of Northumberland, and had a yearly pension: from the former I found two observations of the same comet of 1618, made in Oxford, which he communicated to Mr. Harriot.

"Thomas Harriot died July 2, 1621. His disease was a cancerous ulcer in the lip, which some pretend he got by a custom he had of holding the mathematical brass instruments, when working, in his mouth. I found several of his letters, and answers to them, from his physician Dr. Alexander Rhead, who in his treatise mentions Harriot's disease. His body was conveyed to St. Christopher's church, in London. Over his grave was soon after erected a monument, with a large and suitable inscription, which was destroyed with the church itself by the dreadful fire of September 1666. He was but 60 years of age."

The peculiar nature and merits of Harriot's Algebra, we have spoken largely and particularly of, under the article *Algebra*. As to his manuscripts lately discovered by Dr. Zach, as above mentioned, it is with pleasure I can announce, that they are in a fair train to be published: they have been presented to the university of Oxford, on condition of their printing them; with a view to which, they have been lately put into the hands of an ingenious member of that learned body, to arrange and prepare them for the press. See Wood's *Athenae Oxoniensis*, vol. 1. pa. 390.

HARRIS (JOHN), D. D. and F. R. S. was elected into the Royal Society about the year 1696: became one of the secretaries in 1709, and died Sept. 7, 1719. Dr. Harris published the first real dictionary of the arts and sciences, under the title of *Lexicon Technicum*, in folio, 1699, showing the state of the sciences at that time, a good account of which is given in the Philos. Trans. for 1704, and in my *Abridg.* vol. 5, pa. 149.—Some years after, a 2d volume was added, in a new alphabet, to include the new improvements in science. A 3d volume was afterwards added, but supposed to be a compilation by the booksellers. The whole was a very useful work, and went through several editions. He had some papers inserted in the Philos. Trans. and published several other useful books: as, a neat tract on Algebra, 8vo, 1705; and another on Geometry and Plane Trigonometry, being chiefly a translation from the French of Pardies, the 2d edit. 1702.

About this time it seems that Dr. Harris "lived and

taught mathematics at his house in Amen Corner." He wrote also, A New short Treatise of Algebra; with the Geometrical Construction of Equations, as far as the 4th power or Dimension: together with a specimen of the nature and algorith of Fluxions. This tract is announced to have been written primarily for the use of his auditors at the public mathematical lecture set up at the Marine Coffee-house, Birch-in-lane, by Charles Cox, Esq. M.P. for Southwark. He also published Elements of Plain and Spherical Trigonometry, together with the principles of Spheric Geometry, and the several projections of the Sphere in Plano. Also The Description and Uses of the Celestial and Terrestrial Globes, and of Collins's Pocket Quadrant, 4th edition. He was also the author of a Collection of Voyages, 2 vols. fol. 1705; of which useful work there have been some other editions, particularly one in 1744, much improved by Dr. John Campbell.

Dr. Harris appears to have been a patron of the mathematical Wm. Jones, Esq. the friend of Sir I. Newton, and father of the late learned Sir Wm. Jones, the celebrated Indian judge, as Mr. Jones dedicated to the Rev. Mr. John Harris his Treatise on Navigation, published in 1702, in whose house Mr. Jones says he composed his said book.

HARRISON (JOHN), a most accurate mechanic, the celebrated inventor of the famous *time-keeper* for ascertaining the longitude at sea, and also of the compound or gridiron pendulum; was born at Foulby, near Pontefract in Yorkshire, in 1693. His father was a carpenter, in which profession our author assisted; occasionally also, according to the miscellaneous practice of country artists, surveying land, and repairing clocks and watches; and young Harrison always was from his earliest years, greatly attached to any machinery moving by wheels. In 1700 he removed with his father to Barrow in Lincolnshire; where, though his opportunities of acquiring knowledge were very few, he eagerly improved every incident from which he might collect information; frequently employing all or great part of his nights in writing or drawing: and he always acknowledged his obligations to a clergyman who came every Sunday to officiate in the neighbourhood, who lent him a ms. copy of Professor Sanderson's lectures; which he carefully and neatly transcribed, with all the diagrams. His native genius exerted itself superior to these solitary disadvantages; for in the year 1726, he had constructed two clocks, chiefly of wood, in which he applied the escapement and compound pendulum of his own invention: these surpassed every thing of the kind then made, scarcely erring a second in a month. In 1728, he came up to London with the drawings of a machine for determining the longitude at sea, in expectation of being enabled to execute one by the Board of Longitude. On application to Dr. Halley, the astronomer-royal, he referred him to Mr. George Graham, who advised him to make his machine, before applying to that board. Accordingly our author returned home to perform his task; and in 1735 revisited London with his first machine; with which he was sent to Lisbon the next year, to make trial of it. In this short voyage, he corrected the dead reckoning about a degree and a half; a success which procured him both public and private encouragement. About the year 1739 he completed his second machine, of a construction much more simple than the former, and which answered much better: this, though not sent to sea, recommended

Mr. Harrison yet stronger to the patronage of his friends and the public. His third machine, which he produced in 1749, was still less complicated than the second, and more accurate, as erring only 3 or 4 seconds in a week. This he conceived to be the *re plus ultra* of his attempts; but by endeavouring to improve pocket-watches, he found the principles he applied to surpass his expectations so much, as to encourage him to make his fourth time-keeper, which is in the form of a pocket-watch, about 6 inches diameter. With this time-keeper his son made two voyages, the one to Jamaica, and the other to Barbadoes; in which experiments it corrected the longitude within the nearest limits required by the act of the 12th of Queen Anne; and the inventor had therefore, at different times, more than the proposed reward, receiving from the Board of Longitude at different times almost 24,000*l.* besides a few hundreds from the East India Company, &c. These four machines were given up to the Board of Longitude. The three former were not of any use, as all the advantages gained by making them were comprehended in the last: being worthy however of preservation, as mechanical curiosities, they are deposited in the Royal Observatory at Greenwich. The fourth machine, emphatically distinguished by the name of the time-keeper, was copied by the ingenious Mr. Kendal; and that duplicate, during a three-years circumnavigation of the globe in the southern hemisphere by Captain Cook, answered as well as the original.

The latter part of Mr. Harrison's life was employed in making a fifth improved time-keeper, on the same principles with the preceding one; which, after a ten-weeks trial, in 1772, at the king's private observatory at Richmond, was found to have erred only 4*1/2* seconds. Within a few years of his death, his constitution visibly declined; and he had frequent fits of the gout, a disorder that never attacked him before his 77th year. His constitution at last yielding to the infirmities of old age, he died at his house in Red-Lion Square, in 1776, at 83 years of age.

Our author, like many other mere mechanics, found much difficulty in delivering his sentiments in writing (at least in the latter periods of his life, when his faculties were much impaired), in which he adhered to a peculiar and uncouth phraseology. This was but too evident in his Description concerning such Mechanism as will afford a nice or true Mensuration of Time, &c. 8vo, 1775. In this small work is included also an account of his new musical scale; being a mechanical division of the octave, according to the proportion which the radius and diameter of the circle have respectively to the circumference. He had in his youth been the leader of a band of church-singers; had a very delicate ear for music; and his experiments on sound, with a curious monochord of his own improvement, it has been said were not less accurate than those he was engaged in for the mensuration of time.

HARTSOEKER (NICHOLAS), a Dutch philosopher, born at Gouda, in 1656. After receiving a liberal education under his father, who was a minister under the remonstrants, he applied himself assiduously to mathematics and natural philosophy, and became so eminent that Peter the Great invited him to Moscow, but he declined the honour. He became professor of philosophy at Heidelberg, and mathematician to the Elector Palatine. He died in 1725. Hartsoeker wrote a Course of Natural Philosophy, in 4to; and some small pieces.

HAUTEFEUILLE (JOHN), an ingenious mechanic,

born at Orleans in 1674. He made a great progress in mechanics in general, but had a particular taste for clock-work, and made several discoveries in it that were of singular use. It was he, it appears, who determined the method of moderating the vibration of the balance by means of a small steel spring, which has since been used. This discovery he laid before the members of the Academy of Sciences in 1694; and these watches are, by way of eminence, called pendulum watches; not that they have real pendulums, but because they nearly approach to the justness of pendulums. Huygens has the merit of perfecting this happy invention: but having declared himself the inventor and obtained a patent for making watches with spiral springs, the abbé Feuille opposed the registering of it, and published a piece on the subject against Huygens. He died in 1724, at 50 years of age. Besides the above, he wrote a great many other pieces, most of which are small pamphlets, but very curious: as, 1. His Perpetual Pendulum. 2. New Inventions. 3. The Art of Breathing under Water, and the means of preserving a Flame shut up in a Small Place. 4. Reflections on machines for raising Water. 5. His Opinion on the different Sentiments of Mallebranche and Regis, relating to the Appearance of the Moon when seen in the Horizon. 6. The Magnetic Balance. 7. A Placet to the king on the Longitude. 8. Letter on the Secret of the Longitude. 9. A New System on the Flux and Reflux of the Sea. 10. The means of making Sensible Experiments that prove the Motion of the Earth: and many other pieces.

HAYES (CHARLES, Esq.), a very singular person, whose great erudition was so concealed by his modesty, that his name is known but to few, though his publications are many. He was born in 1678, and died in 1760, at 82 years of age. He became distinguished in 1704 by a Treatise of Fluxions, in folio, being we believe the first treatise on that science ever published in the English language; and the only work to which he ever set his name. In 1710 came out a small 4to pamphlet, in 19 pages, entitled, A New and easy Method of determining the Longitude from observing the Altitudes of the Celestial Bodies. Also, in 1723, he published, The Moon, a philosophical dialogue; tending to show, that the moon is not an opaque body, but has native light of her own.

To a skill in the Greek and the Latin, as well as the modern languages, he added the knowledge of the Hebrew: and he published several pieces relating to the translation and chronology of the Scriptures. During a long course of years he had the chief management of the late African company, being annually elected sub-governor. But on the dissolution of that company in 1752, he retired to Down, in Kent, where he spent most of his hours in study; from whence however he returned, in 1758, to chambers in Gray's-inn, London, where he died in 1760, as mentioned above. He left a posthumous work, that was published in 8vo, under the title of Chronographia Asiatica et Ægyptiaca, &c.

HEAD, in Architecture. Heads are used as an ornament of sculpture or carved work, frequently serving as the key of an arch or platband, and on other occasions.

HEAT, the opposite to cold, being a relative term denoting the property of fire, or of those bodies we denominate hot; being in us a sensation excited by the action of fire.

Heat, as it exists in the hot body, or that which constitutes and denominates a body hot, and enables it to produce such effects on our organs, is variously consider-

ed by philosophers: some making it a quality, others substance, and others only a mechanical affection. The former principle is given and maintained by Aristotle and the Peripatetics. While the Epicureans, and other corpuscularians, define heat not as an accident of fire, but as an essential power or property of it, the same in reality with it, and only distinguished from fire in the manner of our conception. Heat, therefore, on their principles, is no other than the volatile substance of fire itself, reduced into atoms, and emitted in a continual stream from ignited bodies; so as not only to warm the objects within its reach, but also, if they be inflammable, to kindle them, turn them into fire, and conspire with them to make flame. In effect, these corpuscles, observe they, flying off from the ignited body, constitute fire while yet contained within the sphere of its flame; but when fled, or got beyond the same, and dispersed every way, so as to escape the apprehension of the eye, and only to be perceived by the feeling, they take the denomination of heat, inasmuch as they excite in us that sensation.

The Cartesians, improving on this doctrine, assert that heat consists in a certain motion of the insensible particles of a body, resembling the motion by which the several parts of our body are agitated by the motion of the heart and blood.

Our latest and best writers of mechanical, experimental, and chemical philosophy, differ very considerably about heat. The chief difference is, whether it be a peculiar property of one certain immutable body, called fire, or phlogiston, or electricity; or whether it may be produced mechanically in other bodies, by inducing an alteration in their particles. The former tenet, which is as ancient as Democritus, and the system of atoms, had yielded to that of the Cartesians, and other mechanists; but is now with great address retrieved, and improved on, by some of the latest writers, particularly Homberg, the younger Lemery, Gravescande, Boerhaave in his lectures on fire, Black, Crawford, and other chemical philosophers.

That which is denominated fire, according to Boerhaave, is a body sui generis, created such ab origine, unalterable in its nature and properties, and not either producible de novo from any other body, nor capable of being reduced into any other body, or of ceasing to be fire. This fire, he contends, is diffused equally every where, and exists alike, or in equal quantity, in all the parts of space, whether void, or possessed by bodies; but that naturally, and in itself, it is perfectly latent and imperceptible; being only discovered by certain effects which it produces, and which are cognizable by our senses. These effects are heat, light, colour, rarefaction, and burning, which are all indications of fire, as being none of them producible by any other cause; so that wherever we observe any of these, we may safely infer the action and presence of fire. But though the effect cannot be without the cause, yet the fire may remain without any of these effects; any, we mean, gross enough to affect our senses, or become objects of them: and this, he adds, is the ordinary case; there being a concurrence of other circumstances, which are often wanting, necessary to the production of such sensible effects.

Hear, according to the mechanical philosophers, especially Bacon, Boyle, and Newton, is considered not as an original inherent property of any particular kind of body; but as mechanically producible in any body. The former, in an express treatise De Forma Calidi, from

a particular enumeration of the several phenomena and effects of heat, deduces several general properties of it; and hence he defines heat, an expansive undulatory motion in the minute particles of the body; by which they tend, with some rapidity, towards the circumference, and at the same time incline a little upwards.

Mr. Boyle, in a treatise on the mechanical origin of heat and cold, strongly supports the doctrine of the producibility of heat, with new observations and experiments; as in the instance of a smith briskly hammering a small piece of iron, which, though cold at the commencement, soon becomes exceedingly hot.

This system is also further supported by Newton, who does not conceive fire as any particular species of body, originally endued with such and such properties. Fire, according to him, is only a body much ignited, that is heated hot, so as to emit light copiously: what else, observes he, is red-hot iron but fire? and what else is a burning charcoal but red-hot wood? or flame itself, but red-hot smoke? It is certain that flame is only the volatile part of the fuel heated red-hot, i. e. so hot as to shine; and hence only such bodies as are volatile, that is, such as emit a copious fume, will flame; nor will they flame longer than they have fume to burn. In distilling hot spirits, if the head of the still be taken off, the ascending vapours will catch fire from a candle, and turn into a flame. And in the same manner several bodies, much heated by motion, attrition, fermentation, or the like, will emit lucid fumes, which, if they be copious enough, and the heat sufficiently great, will be flame; and the reason why fused metals do not flame, is the smallness of their fume; this is evident, because splinter, which fumes most copiously, does likewise flame. Add, that all flaming bodies, as oil, tallow, wax, wood, pitch, sulphur, &c, by flaming, waste and vanish into burning smoke. And do not all fixed bodies, when heated beyond a certain degree, emit light, and shine? and is not this emission performed by the vibrating motion of their parts? and do not all bodies, which abound with terrestrial and sulphureous parts, emit light as often as those parts are sufficiently agitated, whether that agitation be made by external fire, or by friction, or percussion, or putrefaction, or by any other cause? Thus, sea-water, in a storm; quicksilver agitated in *vacuo*; the back of a cat, or the neck of a horse, obliquely rubbed in a dark place; wood, flesh, and fish, while they putrefy; vapours from putrefying waters, usually called *ignes fatui*; stacks of moist hay or corn; glow-worms; amber and diamonds by rubbing; fragments of steel struck off with a flint, &c, all emit light. Are not gross bodies and light convertible into each other, and may not bodies receive much of their activity from the particles of light which enter their composition? I know no body less apt to shine than water; and yet water, by frequent distillations, changes into fixed earth, which, by a sufficient heat, may be brought to shine like other bodies.

Let it further be considered, that the sun and stars, according to Newton's conjecture, are no other than great earths vehemently heated; for large bodies, he observes, preserve their heat the longest, their parts heating each other: and why may not great, dense, and fixed bodies, when heated beyond a certain degree, emit light so copiously, as by the emission and reaction of it, and the reflections and refractions of the rays within the pores, to grow still hotter, till they arrive at that degree of heat which the sun is of? Their parts also may be further preserved

from fuming away, not only by their fixity, but by the vast weight and density of their atmospheres incumbent on them, thus strongly compressing them, and condensing the vapours and exhalations arising from them. Hence we see warm water, in an exhausted receiver, to boil as vehemently as the hottest water exposed to the air; the weight of the incumbent atmosphere, in this latter case, keeping down the vapours, and hindering the ebullition, till it has acquired its utmost degree of heat. So also a mixture of tin and lead, put on a red-hot iron in *vacuo*, emits a fume and flame; but the same mixture in the open air, by reason of the incumbent atmosphere, does not emit the least sensible flame.

Thus much for the system of the producibility of heat. On the other hand, M. Homberg, in his *Essai du Soufre Principe*, holds, that the chemical principle or element, sulphur, which is supposed one of the simple, primary, pre-existent ingredients of all natural bodies, is real fire; and consequently that fire is co-eval with body. Mem. de l'Acad. an. 1705.

Dr. Gravesande goes upon much the same principle. According to him, fire enters the composition of all bodies, is contained in all bodies, and may be separated or procured from all bodies, by rubbing them against each other, and thus putting their fire in motion. But fire, he adds, is by no means generated by such motion. Elein. Phys. tom. 2, cap. 1. Heat, in the hot body, he observes, is an agitation of the parts of the body, made by means of the fire contained in it; by such agitation a motion is produced in our bodies, which excites the idea of heat in our minds: so that heat, in respect of us, is nothing but that idea, and in the hot body nothing but motion. If such motion expel the fire in right lines, it may give us the idea of light; if in a various and irregular motion, only that of heat.

Lemery, the younger, agrees with these two authors, in asserting this absolute and ingenerable nature of fire; but he extends it farther. Not contented with confining it as an element to bodies, he endeavours to show, that it is equally diffused through all space; that it is present in all places, even in the void spaces between the bodies, as well as in the insensible interstices between their parts. And this last sentiment falls in with that of Boerhaave above delivered. Mem. de l'Acad. an. 1713.

Philosophers have lately distinguished heat into absolute and sensible. By absolute heat, or fire, they mean that power or element which, when it is in a certain degree, excites in animals the sensation of heat; and by sensible heat, the same power considered in its relation to the effects it produces; thus, two bodies are said to have equal quantities of sensible heat, when they produce equal effects upon the mercury in the thermometer; but as bodies of different kinds have different capacities for containing heat, the absolute heat in such bodies will be different, though the sensible heat be the same. Thus, a pound of water and a pound of antimony, of the same temperature, have equal sensible heat; but the former contains a much greater quantity of absolute heat than the latter.

M. DeLuc has evinced, by a variety of experiments, that the expansions of mercury between the freezing and boiling points of water, correspond precisely to the quantities of absolute heat applied, and that its contractions are proportionable to the diminution of this element within these limits. And hence it may be inferred, that if the mercury were to retain its fluid form, its contractions would

be proportionable to the decrements of the absolute heat, though the diminution were continued to the point of total privation. But the comparative quantities of absolute heat, which are communicated to different bodies, or separated from them, cannot be determined in a direct manner by the thermometer.

Some philosophers have apprehended that the quantities of absolute heat in bodies, are in proportion to their densities. While others, as Boerhaave, imagined that heat is equally diffused through all bodies, the densest as well as the rarest, and therefore that the quantities of heat in bodies, are in proportion to their bulk or magnitude: and, at his desire, Fahrenheit attempted to determine the fact by experiment. For this purpose, he took equal quantities of the same fluid, and gave them different degrees of heat; then upon mixing them intimately together, he found that the temperature of the mixture was a just medium, or arithmetical mean, between the two. But if this experiment be made with water and mercury, in the same circumstances, viz, in equal bulks, the result will be different, as the temperature of the mixture will not be a mean between the two, but always nearer to that of the water than to the quicksilver; so that, when the water is the hotter, the temperature of the mixture is above the mean, and below it when the water is the colder. And from experiments of this kind it has been inferred, that the comparative quantities of the absolute heats of these fluids, are reciprocally proportional to the changes which are produced in their sensible heats, when they are mixed together at different temperatures: and this fact has been publicly taught, for several years, by Dr. Black and Dr. Irvine, in the universities of Edinburgh and Glasgow. This rule however does not apply to those substances which, in mixture, excite sensible heat by chemical action.

From the experiments and reasoning employed by Dr. Crawford, it more fully appears, that the quantities of absolute heat in different bodies, are not as their densities; or that equal weights of heterogeneous substances, as air and water, having the same temperature, may contain unequal quantities of absolute heat: he also shows, that if phlogiston be added to a body, a quantity of the absolute heat of that body will be extricated; and if the phlogiston be separated again, an equal quantity of heat will be absorbed. So that heat and phlogiston appear to be two opposite principles in nature. But this ingenious writer has not presumed absolutely to decide the question that has been long agitated, whether heat be a substance or a quality.—He inclines to the former opinion, however, and observes, that if we adopt the opinion, that heat is a distinct substance, or an element *sui generis*, the phenomena will be found to admit of a simple and obvious interpretation, and to be perfectly agreeable to the analogy of nature. See Crawford's Experiments and Observations on Animal Heat and the Inflammation of Combustible Bodies. Also Mr. Leslie's ingenious treatise upon heat; Scheele's Experiments on Air and Fire; Thomson's Chemistry, vol. 1; Boerhaave's Chemistry; Davy's Essays; Rumford's Essays, &c; Herschel's in Phil. Trans.; several vols. of the Philos. Magazine, and in Nicholson's Journal.

Animal Heat. The heat of animals is very various, both according to the diversity of their kinds, and the difference of the seasons: accordingly, zoologists have divided them into hot and cold blooded, reckoning those to be hot that are near or above our own temperature, and all others cold whose heat is below ours, and consequently

affect us with the sense of cold; thus making the human species a medium between the hot and cold blooded animals, or at least the lowest order of the hot blooded.

The heat of the human body, in its natural state, according to Dr. Boerhaave, is such as to raise the mercury in the thermometer to 92° or at most to 94° ; and Dr. Pitcairn makes the heat of the human skin the same. Indeed it is evident that different parts of the human body, and its different states, as well as the different seasons, will make it show of different temperatures. Thus, by various experiments at different times, the heat of the human body is made various by the following authors:

Boerhaave and Pitcairn	-	-	-	-	92°
Amontons	-	-	-	$91, 92,$ or 93	
Sir Isaac Newton	-	-	-	-	95°

at 2 inches	-	-	-	-	93
at 4 inches	-	-	-	-	94
the ball of the thermometer, at the bulb of the urethra					97

For the powers of animals to bear various degrees of heat, see the Philos. Trans. vol. 65, 68, &c. There is hardly any subject of philosophical investigation that has afforded a greater variety of hypotheses, conjectures, and experiments, than the cause of animal heat. The first opinion which has very generally obtained, is, that the heat of animal bodies is owing to the attrition between the arteries and the blood. All the observations and reasoning brought in favour of this opinion however, only show that the heat and the motion of the arteries are generally proportional to each other; without showing which is the cause, and which the effect; or indeed that either is the cause or effect of the other, since both may be the effects of some other cause. Dr. Douglas, in his Essay on the Generation of Heat in animals, ascribes it solely to the friction of the globules of blood in their circulation through the capillary vessels. Another opinion is, that the lungs are the fountain of heat in the human body: and this opinion is supported by much the same kind of arguments as the former, and seemingly to little better purpose.

A third opinion is, that the cause of animal heat is owing to the action of the solid parts upon one another. And as the heart and arteries have the most motion, it has been thought natural to expect that the heat should be owing to this motion. But even this does not seem very plausible, from the following considerations: 1st, The moving parts, however we term them solid, are neither hard nor dry; which two conditions are absolutely requisite to make them fit to generate heat by attrition. 2d, None of their motions are swift enough to promise heat in this way. 3d, They have but little change of surface in their attritions. And 4thly, The moveable fibres have fat, incilage, or liquors every way surrounding them, to prevent their being destroyed, or heated by attrition.

Another cause assigned for the heat of our bodies, is that process by which our aliment and fluids are perpetually undergoing some alteration. And this opinion is chiefly supported by Dr. Stevenson, in the Edinburgh Medical

Essays, vol. 5, art. 77. The late ingenious Dr. Franklin inclines to this opinion, when he says, that the fluid fire, as well as the fluid air, is attracted by plants in their growth, and becomes consolidated with the other materials of which they are formed, and makes a great part of their substance; that when they come to be digested, and to undergo a kind of fermentation in the vessels, part of the fire, as well as part of the air, recovers its fluid active state again, and diffuses itself on the body digesting and separating it; &c. Exper. and Obs. on Electricity, pa. 346.

Dr. Mortimer thinks the heat of animals explicable from the phosphorus and air they contain. Phosphorus exists, at least in a dormant state, in animal fluids; and it is also known that they all contain air; it is therefore only necessary to bring the phosphoreal and aerial particles into contact, and heat must of consequence be generated; and were it not for the quantity of aqueous humours in animals, fatal accensions would frequently happen. Philos. Trans. No. 476.

Dr. Black supposes, that animal heat is generated entirely in the lungs, by the action of the air on the principle of inflammability, and is thence diffused over the rest of the body by means of the circulation. But Dr. Leslie urges several arguments against this hypothesis, tending to show that it is repugnant to the known laws of the animal machine; and he advances another hypothesis instead of it, viz, that the subtle principle by chemists termed phlogiston, which enters into the composition of natural bodies, is in consequence of the action of the vascular system gradually evolved through every part of the animal machine, and that during this evolution heat is generated. This opinion, he candidly acknowledges, was first delivered by Dr. Duncan of Edinburgh; and that something similar to it is to be found in Dr. Franklin's works, and in a paper of Dr. Mortimer's in the Philos. Trans.

The last hypothesis we shall mention, is the very plausible one of Dr. Crawford, lately published in his Experiments and Observations on Animal Heat. This ingenious gentleman has inferred, from a variety of experiments, that heat and phlogiston, so far from being connected, as most philosophers have imagined, act in some measure in opposition to each other. By the action of heat on bodies, the force of their attraction of phlogiston is diminished, and by the action of phlogiston, a part of their absolute heat is expelled. He has also demonstrated, that atmospherical air contains a greater quantity of absolute heat than the air which is expired from the lungs of animals: he makes the proportion of the absolute heat of atmospherical air to that of fixed air, as 67 to 1; and the heat of dephlogisticated air to that of atmospherical air, as 4:6 to 1; and observing that Dr. Priestley has proved, that the power of this dephlogisticated air in supporting animal life, is 5 times as great as that of atmospherical air, he concludes that the quantity of absolute heat contained in any kind of air fit for respiration, is very nearly in proportion to its purity, or to its power of supporting animal life; and since the air exhaled by respiration, is found to contain only the 67th part of the heat which was contained in the atmospherical air, previous to inspiration, it is very reasonably inferred, that the latter must necessarily deposit a very great proportion of its absolute heat in the lungs. Dr. Crawford has also shown, that the blood which passes from the lungs to the heart, by the pulmonary vein, contains more absolute heat than that which passes from the heart to the lungs, by the pulmonary artery; the abso-

lute heat of florid arterial blood being to that of venous blood, as 11½ to 10: therefore, since the blood which is returned by the pulmonary vein to the heart has the quantity of its absolute heat increased, it must have acquired this heat in its passage through the lungs; so that in the process of respiration a quantity of absolute heat is separated from the air, and absorbed by the blood. Dr. Priestley has also proved, that in respiration, phlogiston is separated from the blood, and combined with air.

This theory however has been contested and disputed, and it has been said, Dr. Crawford's experiments repeated, with contrary results. Though no regular and systematical theory has yet been formed in its stead.

Heat of Combustible and Inflammable Bodies. Dr. Crawford's theory with respect to the inflammation of combustible bodies, is founded on the same principles as his doctrine concerning the heat of animals. According to him, the heat which is produced by combustion, is derived from the air, and not from the inflammable body. Inflammable bodies, he says, abound with phlogiston, and contain little absolute heat; the atmosphere, on the contrary, abounds with absolute heat, and contains little phlogiston. In the process of inflammation, the phlogiston is separated from the inflammable body, and combined with the air; the air is phlogisticated, and affords a great proportion of its absolute heat, which, when extricated suddenly, bursts forth into flame, and produces an intense degree of sensible heat. And since it appears by calculation, that the heat produced by converting atmospherical into fixed air, is such, if it were not dissipated, as would be sufficient to raise the air so changed, to more than 12 times the heat of red-hot iron, it follows, that in the process of inflammation a very great quantity of heat is derived from the air. But, on the contrary, no part of the heat can be derived from the combustible body; because this body, during the inflammation, being deprived of its phlogiston, undergoes a change similar to that of the blood by the process of respiration, in consequence of which its capacity for heat is increased; and therefore it will not evolve any part of its absolute heat, but, like the blood in its passage through the lungs, it will absorb heat. A similar theory of heat has lately been published by Mr. Elliot. See his Philosophical Observations on the Senses of Vision and Hearing; to which is added an Essay on Combustion and Animal Heat, 8vo, 1780. See CALORIC, also Professor Leslie's late work on heat.

Mr. Ezekiel Walker has given a neat account of the causes and mode of combustion, in the Philos. Magazine, vol. 43, pa. 101, as follows. There are very few bodies in nature that do not contain either thermogen or photogen. All those bodies which are called combustibles, contain the element of light, which I call photogen, to avoid the use of ambiguous terms; and all those bodies which are called supporters of combustion, contain the generator of heat, called thermogen for the same reason. These elements may be made to unite and produce combustion, or increase the temperature of bodies, by various means; as: 1st, by friction; 2dly, by percussion; 3dly, by pressure; 4thly, by mixture; 5thly, by increase of temperature; and 6thly, by the functions of living animals and vegetables.

Thermogen and photogen in a condensed state, as in a charged Leyden jar, have so strong an attraction for each other, that they will pass through any of those bodies called conductors, to a very great distance, to be united.

But when they are united to ponderable matter, they will remain mixed together for ages without producing any effect; but as soon as they are brought within a certain distance of each other, which may be called their striking distance, or their sphere of action, either combustion takes place, or the temperature of the body, in which they meet, is increased. The following explanations of some well-known experiments will tend to show the importance of a theory founded on facts.

Exper. 1. In a memoir read to the National Institute of France, M. Biot announces the important fact, that a mixture of hydrogen and oxygen gases may be made to explode by mechanical compression only, independently of the electric spark.—*Explanation.* Oxygen and hydrogen gases would remain mixed together, for any length of time, without combining, the thermogen and photogen in them being kept at too great a distance by their bases; but, by mechanical compression only, they are forced within their striking distance, and light and heat are produced on the same principle as combustion is produced by discharging a Leyden jar.

Exper. 2. Take 6 grains of oxygenized muriate of potass, and 3 grains of flour of sulphur, rub them together in a mortar, and a smart detonating noise will be produced. Continue to rub the mixture hard, and the report will be frequently repeated, accompanied with vivid flashes of light. If the same mixture be wrapped in paper, laid on an anvil, and smartly struck with a hammer, the report will be as loud as that of a pistol.—*Explan.* These experiments may be explained on the same principle as the last. The two ingredients, though mixed together, produced no effect until the thermogen in one of them and the photogen in the other were forced into union, by friction or percussion. And on the same principle the effects of many other fulminating substances may be explained.

Exper. 3. If an ounce of strong nitrous acid be mixed with about half its weight of sulphuric acid, and poured into a little oil of turpentine, the whole will immediately burst into flame.—*Explan.* The thermogen and photogen in these fluids coming immediately into contact, flame is produced, without any mechanical force or increase of temperature.—Now, from this experiment it appears impossible that water can be a compound of oxygen and hydrogen; for, if it were, these two principles of combustion would burst into flame like the acid and the oil. But no pressure, no increase of temperature, nor any union with combustible matter, can produce a single spark of fire from water. In short, nothing combustible is found in its composition.

Exper. 4. Combustion may also be generated by friction. Two pieces of hard wood, being smartly rubbed together with great pressure, will soon burst into flame.—*Explan.* The first increment of caloric, by friction, is excited by a portion of the thermogen of the air being forced into union with the photogen in the wood; and by continuing the operation, the temperature of the inflammable principle of the wood is increased till flame is produced.

Exper. 5. When a rod of iron is laid upon an anvil, and hammered with a quick succession of heavy strokes, it soon becomes red-hot. But it cannot be strongly heated a second time by the same means, unless it be first introduced into a fire.—*Explan.* The first stroke of the hammer forces a small portion of the thermogen of the air into contact with the photogen of the metal, which generates

the first increment of caloric; and by repeated strokes of the hammer the caloric is increased, till the rod becomes red-hot. But the photogen of the metal becomes exhausted by this means, and therefore cannot produce caloric a second time, till it has recovered its combustible property in the fire.—The burning of iron wire in oxygen gas, in a brilliant manner shows how iron loses its photogen, and becomes oxydized.

Exper. 6. Mr. Thomas Wedgwood has shown, that it has never yet been explained, how friction produces caloric. He took a piece of common window-glass, and held the edge of it against the edge of a revolving grit-stone, when that part in contact with the stone became red-hot, and threw off hot particles which fired gunpowder. The stone and the glass being both incombustible substances, it remains to be explained how caloric was produced.—*Explan.* It has before been shown, that the electric machine creates nothing, but by friction only collects the two elements which produce caloric, from the earth and the atmosphere. Though the stone and the glass, in Mr. W.'s experiment, are both incombustible, yet it is almost a self-evident conclusion, that they collect the two elements of caloric from the air and the earth by friction, in the same manner as the electric machine.

Exper. 7. It is well known, that when flint and steel are smartly struck against each other, a spark always ensues, which is capable of setting fire to tinder or to gunpowder. The spark in this case, as was long since ascertained by Dr. Hooke, is a small particle of the metal, which is struck off, and takes fire during its passage through the air. This therefore, and all similar cases, belongs to the class of combustion. But light often appears when two bodies are struck against each other, when we are certain that no such thing as combustion can happen, because both the bodies are incombustible. Thus, for instance, sparks are emitted when two quartz stones are struck smartly against each other, and light is emitted when they are rubbed against each other. Many other hard stones also emit sparks by such collisions.—If they be often made to emit sparks above a sheet of white paper, there are found upon it a number of small black bodies, somewhat like the eggs of flies. These bodies are hard, but friable, and leave a black stain when rubbed on the paper. When viewed with a microscope, they seem to have been melted. Muriatic acid changes their colour to a green, as it does that of lavas. These substances evidently produced the sparks by being heated red-hot.—*Explan.* It may first be observed, that if the flint be moved over the stone very slowly, no spark is produced, nor will any spark appear if the flint barely touch the steel, though the velocity of the flint be the greatest possible: consequently, caloric cannot be produced by collision or friction, but by velocity and pressure conjointly.—2dly, By the collision of the flint and steel, the thermogen of the atmosphere is forced into union with the photogen of the metal. The combination thus produced melts the minute particles of steel, struck off by the flint, into small globules. That this metal contains the generator of light is well known, by the burning of iron or steel wire in oxygen gas.—Sparks are emitted when two quartz stones are struck smartly against each other under water; and Mr. Kirwan affirms, that sparks are produced by the collision of flint and steel under common spring water.

Exper. 8. From Count Rumford's experiments it appears, that by a moderate degree of friction, the same

piece of metal afforded so much caloric under water, as to keep it boiling.—*Explan.* This experiment may be explained on the same principle as the last. Water, being a better conductor of thermogen than atmospheric air, cannot prevent the production of caloric by the collision or friction of hard bodies.

H E A T, in *Geography*, is that which relates to the earth. There is a great variety in the heat of different places and seasons. Naturalists have commonly assumed it as a fact, that the nearer any place is to the centre of the earth, the hotter it is found; but this does not appear to hold strictly true. And if it were, the effect might be otherwise accounted for, and more satisfactorily, than from their imagined central fire.

Mr. Boyle, who had been at the bottom of some mines himself, with more probability suspects that this degree of heat, at least in some of them, may arise from the peculiar nature of the minerals there produced. And he instances a mineral of the vitriolic kind, dug up in large quantities, in several parts of England, which, by the bare effusion of common water, will become so hot as almost to take fire. To which may be added, that such places, in the bowels of the earth, usually feel hot, from the confined and stagnant state of the air in them, in which the heat is retained, for want of a current or change of air to carry the heat off.

On the other hand, on ascending high mountains, the air feels more and more cold and piercing. Thus, the tops of the Pike of Teneriffe, the Alps, and several other mountains, even in the most sultry countries, are found always invested with snow and ice, which the heat is never sufficient to thaw. In some of the mountains of Peru there is no such thing as running water, but all ice: plants vegetate a little about the bottom of the mountains, but near the top no vegetable can live, for the intenseness of the cold. This effect is attributed to the thinness of the air, and the little surface of the earth there is to reflect the rays, as well as the great distance of the general surface of the earth which reflects the rays back into the atmosphere.

As to the diversity in the heat of different climates and seasons, it arises from the different angles under which the sun's rays strike upon the surface of the earth. In the Philos. Trans. Abr. vol. 3, p. 576, Dr. Halley has given a computation of this heat, on the principle, that the simple action of the sun's rays, like other impulses or strokes, is more or less forcible, according to the sines of the angles of incidence, or to the sines of the sun's altitudes, at different times or places.

Hence it follows, that the time of continuance, or the sun's shining on any place, being taken for a basis, and the sines of the sun's altitudes perpendicularly erected upon it, and a curve line drawn through the extremities of those perpendiculars, the area thus comprehended will be proportional to the collection of all the heat of the sun's beams in that period of time.

Hence it will likewise follow, that at the pole, the collection of all the heat of a tropical day, is proportional to the rectangle or product of the sine of $23\frac{1}{2}$ degrees into 24 hours, or the circumference of a circle, or as $\frac{\pi}{2}$ into 12 hours, the sine of $23\frac{1}{2}$ degrees being nearly $\frac{4}{5}$ of radius. Or the polar heat will be equal to that of the sun continuing 12 hours above the horizon at 53 degrees height; and the sun is not 5 hours more elevated than this under the equinoctial.

But as it is the nature of heat to remain in the subject,

after the luminary is removed, and particularly in the air, under the equinoctial, the 12 hours absence of the sun abates but little from the effect of his heat in the day; but under the pole, the long absence of the sun for 6 months has so chilled the air, that it is in a manner frozen, and after the sun has risen upon the pole again, it is long before his beams can make any impression, being obstructed by thick clouds and fogs.

From the foregoing principle Dr. Halley computes the following table, exhibiting the heat to every 10th degree of latitude, for the equinoctial and tropical sun, and from which an estimate may easily be made for the intermediate degrees.

Latitude.	Sign that the Sun is in.		
	γ or Δ	\odot	γ
0	20000	18341	18341
10	19696	20296	15834
20	18794	21737	13166
30	17321	22651	10124
40	15321	23048	6944
50	12855	22991	3798
60	10000	22773	1075
70	6840	23543	0
80	3473	24673	0
90	0	25055	0

From the same principles, and table, also are deduced the following corollaries, viz,

1. That the equatorial heat, when the sun becomes vertical, is as twice the square of the radius.—2. That at the equator the heat is as the sine of the sun's declination.—3. That in the frigid zones, when the sun sets not, the heat is as the circumference of a circle into the sine of the altitude at 6°: And consequently, that in the same latitude, these aggregates of heat are as the sines of the sun's declination; and at the same declination of the sun, they are as the sines of the latitudes; and generally they are as the sines of the latitudes into the sines of declination.—4. That the equatorial day's heat is every where as the cosine of the latitude.—5. In all places where the sun sets, the difference between the summer and winter heats, when the declinations are contrary, is equal to a circle into the sine of the altitude at 6°, in the summer parallel; and consequently those differences are as the rectangles of the sines of the latitude and declinations.—6. The tropical sun has the least force of any at the equator; and at the pole it is greatest of all.

Many objections have been urged against this theory of Dr. Halley. Some have insisted, that the effect of the sun's heat is not in the simple, but in the duplicate ratio of the sines of the angles of incidence; like the law of the impulse of fluids. And indeed, the quantity of the sun's direct rays received at any place, being evidently as the sine of the angle of incidence, or of the sun's altitude, if the heat be also proportional to the force with which a ray strikes, like the mechanical action or impulse of any body, then it will follow that the heat must be in the compound ratio of both, that is, as the square of the sine of the sun's altitude. But this last principle is here only assumed gratis, as we do not know a priori that the heat is proportional to the force of a striking body; and it is only experiment that can determine this point.

It is certain that heat communicated by the sun to bo-

dies on the earth, depends also much upon other circumstances beside the direct force of his rays. These must be modified by our atmosphere, and variously reflected and combined by the action of the earth's surface itself, to produce any remarkable effects of heat. So that, if it were not for these additional circumstances, it is probable the naked heat of the sun would not be very sensible.

Dr. Halley himself was well apprised, that many other circumstances, besides the direct force of the sun's rays, contributed to augment or diminish the effect of this, and the heat resulting from it, in different climates; and therefore no calculation, formed on the preceding theory, can be supposed to correspond exactly with observation and experiment. It has also been objected that, according to the foregoing theory, the greatest heat in the same place, should be at the summer solstice, and the most extreme cold at the winter solstice; which is contrary to experience. To this objection it may be replied, that heat is not produced in bodies by the sun instantaneously, nor do the effects of his heat cease immediately when his rays are withdrawn; and therefore those parts which are once heated, retain the heat for some time; which, with the additional heat daily imparted, makes it continue to increase, though the sun declines from us: and this is the reason why July is hotter than June, though the sun has withdrawn from the summer tropic: as we also find it is generally hotter at one, two, or three in the afternoon, when the sun has declined towards the west, than at noon, when he is on the meridian. As long as the heating particles, which are constantly received, are more numerous than those which fly away or lose their force, the heat of bodies must continually increase. So, after the sun has left the tropic, the number of particles, which heat our atmosphere and earth, constantly increases, because we receive more in the day than we lose at night, and therefore our heat must also increase. But as the days decrease again; and the action of the sun becomes weaker, more particles will be dispersed in the night than are received in the day, by which means the earth and air will gradually cool. Further, those places which are well cooled, require time to be heated again; and therefore January is mostly colder than December, though the sun has withdrawn from the winter tropic, and begun to emit his rays more directly upon us.

But the chief cause of the difference between the heat of summer and winter is, that in summer the rays fall more directly, and pass through a less dense part of the atmosphere; and therefore with greater force, or at least in greater number in the same place: and besides, by their long continuance, a much greater degree of heat is imparted by day than can be dispersed by night. For the calculations and opinions of several other philosophers on this head, see Keill's Astron. Lect. 8; Ferguson's Astron. chap. 10; Long's Astron. § 777; Memo. Acad. Scien. 1719.

As to the temperature or heat of our atmosphere, it may be observed that the mercury seldom falls under 16° in Fahrenheit's thermometer; but we are apt to reckon it very cold at 24° , and it continues chilly to 40° and a little above. However, such colds have been often known to reduce it down to 0° , the beginning of the scale, or nearly the cold produced by a mixture of snow and salt, often near it, and in some places below it. Thus, the degree of the thermometer has been observed at various times and places as follows:

Place	Latit.	Year	Thermom.
Pensylvania	$40^{\circ} 0'$	1732	5°
Paris	$48^{\circ} 50'$	1709 & 1710	8
Leyden	$52^{\circ} 10'$	1729	5
Utrecht	$52^{\circ} 8'$	—	4
London	$51^{\circ} 31'$	1709 & 1710	0
Copenhagen	$55^{\circ} 43'$	1709	0
Upsal	$59^{\circ} 56'$	1732	—1
Petersburg	$59^{\circ} 56'$	—	—28
Torneo	$65^{\circ} 51'$	1736—7	—33
Hudson's Bay	$52^{\circ} 24'$	1775	—37

The middle temperature of our atmosphere is about 48° , being nearly a medium of all the seasons. The French make it somewhat higher, reckoning it equal to the cave of their royal observatory, or 53° . In cold countries, the air is found agreeable enough to the inhabitants while it is between 40 and 50° . But in our climate we are best pleased with the heat of the air from 50 to 60° ; while in the hot countries the air is generally at a medium about 70° . With us, the air is not reckoned warm till it arrives about 64° , and it is very warm and sultry at 80° . It is to be noted that the foregoing observations are to be understood of the state of the air in the shade; for as to the heat of bodies acted on by the direct rays of the sun, it is much greater: thus, Dr. Martine found dry earth heated to above 120° ; but Dr. Hales found a very hot sun-shine heat in 1727 to be about 140° ; and Muschenbroek once observed it so high as 150° ; but at Montpelier the sun was so very hot, on one day in the year 1705, as to raise M. Amontons' thermometer to the mark of boiling water itself, which is our 212° . (See Temperature of the Atmosphere under the article ATMOSPHERE.)

It appears from the register of the thermometer kept at London by Dr. Heberden for 9 years, viz, from the end of 1763 to the end of 1772, that the mean heat at 8 in the morning was $47^{\circ} 4'$; and by another register kept at Hawkhill near Edinburgh, that the mean heat in that place, during the same period of time, was 46° . Also by registers kept in London and at Hawkhill, for the three years 1772, 1773, 1774, it appears, that the mean heat of these three years in London, at 8 in the morning, was $48^{\circ} 5'$, and at 2 in the afternoon 56° , but the mean of both morning and afternoon $52^{\circ} 2'$; while the mean heat at Hawkhill for the same time,

at 8 in the morning was	$45^{\circ} 4'$
and at 2 in the afternoon	$50^{\circ} 1'$
and the mean of both	$47^{\circ} 7'$

The mean heat of springs near Edinburgh is found to be about 47° , and at London 51° . Philos. Trans. vol. 65, art. 44.

Lastly, from the meteorological journals of the Royal Society, published in the Philos. Trans., it appears that the mean heights of the thermometer, for the whole years, kept without and within the house, are as below:

	Therm. Without	Therm. Within
For 1775	$51^{\circ} 5'$	$52^{\circ} 7'$
1776	$51^{\circ} 1'$	$52^{\circ} 9'$
1777	$51^{\circ} 0'$	$53^{\circ} 0'$
1778	$52^{\circ} 0'$	$53^{\circ} 1'$
mean of all	$51^{\circ} 4'$	$52^{\circ} 9'$

HEAT, Latent, is insensible, concealed, dormant as it were.

HEAVEN, an azure transparent orb investing our earth, where the celestial bodies perform their motions. It is of divers denominations, as the highest or empyrean

heaven, the ethereal or starry heaven, the planetary heaven, &c. Formerly the heavens were considered as solid substances, or else as spaces full of solid matter; but Newton has abundantly shown that the heavens are void of almost all resistance, and consequently of almost all matter: this he proves from the phenomena of the celestial bodies; from the planets persisting in their motions, without any sensible diminution of their velocity; and the comets freely passing in all directions towards all parts of the heavens. Heaven, taken in this general sense, or the whole expanse between our earth and the remotest regions of the fixed stars, may be divided into two very unequal parts, according to the matter occupying them; viz, the atmosphere or aerial heaven, occupied by air; and the ethereal heaven, possessed by a thin and unresisting medium, called ether.

HEAVEN is more particularly used, in Astronomy, for an orb, or circular region, of the ethereal heaven.

The ancient astronomers assumed as many different heavens as they observed different celestial motions. All these they made solid, thinking they could not otherwise sustain the bodies fixed in them; and of a spherical form, as being the most proper for motion. Thus they had seven heavens for the seven planets; viz, the heavens of the Moon, Mercury, Venus, the Sun, Mars, Jupiter, and Saturn. The 8th was for the fixed stars, which they particularly called the firmament. Ptolemy added a 9th heaven, which he called the primum mobile. After him two crystalline heavens were added by King Alphonsus, &c, to account for some irregularities in the motions of the other heavens. And lastly an empyrean heaven was drawn over the whole for the residence of the Deity; which made the number 12. But some admitted many other heavens, according as their different views and hypotheses required. Eudoxus supposed 23, Calippus 30, Regiomontanus 33, Aristotle 47, and Fracastor no less than 70. The astronomers however did not much concern themselves whether the heavens they thus allowed, were real or not; provided they served a purpose in accounting for any of the celestial motions, and agreed with the phenomena.

HEAVINESS, the same as Gravity, which see.

Heavy bodies do not tend precisely to the very centre of the earth, except at the poles and the equator, on account of the spheroidal figure of the earth; their direction being every where perpendicular to the surface of the spheroid.

HEGIRA, a term in Chronology, signifying the epoch, or account of time, used by the Mahomedans, who begin their computation from the day that Mahomet was forced to make his escape from the city of Mecca, which happened on Friday the 16th of July 622.

The years of the hegira are lunar ones, consisting only of 354 days. Hence, to reduce these years to the Julian calendar, that is, to find what Julian year a given year of the hegira answers to: reduce the year of the hegira into days, by multiplying by 354, divide the product by 365 $\frac{1}{4}$, and to the quotient add 622, the year the hegira commenced.

HEIGHT, the third dimension of a body, considered with regard to its elevation above the ground; or any distance above the earth's surface, &c.

HEIGHT, of a figure, the same as its altitude, being the perpendicular from its vertex to the base.

HEIGHT, of the pole, &c. See *Altitude of the Pole*, &c.
VOL. I.

HELIACAL, something relating to the sun. Thus, **HELIACAL Rising**, of a star or planet, is when it rises with, or at the same time as, the sun. And heliacal setting, the same as the setting with the sun. Or, a star rises heliacally, when, after it has been in conjunction with the sun, and so invisible, it gets at such a distance from him, as to be seen in the morning before the sun's rising. And it is said to set heliacally, when it approaches so near the sun as to be hid by his beams. So that, in strictness, the heliacal rising and setting are only an apparition and occultation.

HELICE Major and **Minor**; the same as *Ursa Major* and *Minor*.

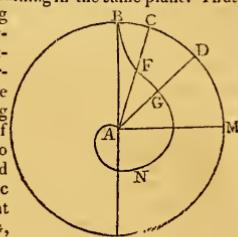

HELICOID Parabola, or the *Parabolic Spiral*, is a curve arising from the supposition that the common or Apollonian parabola is bent or twisted, till the axis come into the periphery of a circle, the ordinate still retaining their places and perpendicular positions with respect to the circle, all these lines still remaining in the same plane. Thus, the axis of a parabola being bent into the circumference $BCDM$, and the ordinates CF , DG , &c, still perpendicular to it, then the parabola itself, passing through the extremities of the ordinates, is twisted into the curve BFG , &c, called the Helicoid, or Parabolic Spiral. Hence it is evident that all the ordinates CF , DG , &c, tend to the centre of the circle, being perpendicular to the circumference.—Also, the equation of the curve remains the same as when it was a parabola; viz, putting $x = \text{any circular absciss } BC$, and $y = CF$ the corresponding ordinate, then is $px = y^2$, where p is the parameter of the parabola.

HELIOCENTRIC Place of a Planet, is the place in which a planet would appear to be when viewed from the sun; or the point of the ecliptic, in which a planet viewed from the sun would appear to be. And therefore the heliocentric place coincides with the longitude of a planet viewed from the sun.

HELIOCENTRIC Latitude of a Planet, is the inclination of the line drawn between the centre of the sun and the centre of a planet, to the plane of the ecliptic. The greatest heliocentric latitude is equal to the inclination of the planet's orbit to the plane of the ecliptic.

HELIOCOMETE, Comet of the Sun, a phenomenon sometimes observed at the setting of the sun; thus denominated by Sturmius and Pylcn, who had seen it, because it seems to make a comet of the sun, being a large tail, or column of light, fixed or attached to that luminary, and dragging after it, at its setting, like the tail of a comet.

HELIOMETER, or **ASTROMETER**; an instrument for measuring, with particular exactness, the diameters of the sun, moon, and stars.—This instrument was invented by M. Bouguer in 1747, and is a kind of telescope, consisting of two object-glasses of equal focal distance, placed by the side of each other, so that the same eye-glass serves for both. The tube of this instrument is of a conical form, larger at the upper end, which receives the two object-glasses, than at the lower, which is furnished with an eye-glass and micrometer. By the construction

of this instrument, two distinct images of an object are formed in the focus of the eye-glass, whose distance, depending on that of the two object-glasses from each other, may be measured with great accuracy. Mem. Acad. Sci. 1748. Mr. Servington Savery discovered a similar method of improving the micrometer, which was communicated to the Royal Society in 1743.

HELIOSCOPE, a kind of telescope peculiarly adapted for viewing and observing the sun without hurting the eye. There are various kinds of this instrument, usually made by employing coloured glass for the object- or eye-glass, or both; and sometimes only using an eye-glass blackened by bolding it over the smoke or flame of a lamp or candle, which is Huygen's way. See Dr. Hooke's treatise on Helioscopes.

HELIOSTATA, an instrument invented by Dr. Gravestane, and so-called from its property of fixing the sunbeam in one position, viz. in a horizontal direction across the dark chamber while it is used. See Gravesande's Physics Element. Mathematica, tom. 2, pa. 715, ed. 3ta, 1742, for an account of the principles, construction and use of this instrument.

HELIOSPHERICAL Line, is the rhumb-line in navigation; being so called, because on the globe it winds round the pole heliacally or spirally, approaching always nearer and nearer to it.

HELIX, a spiral line. See **SPRAL**.

HEMICYCLE, in Architecture, a term applied to semicircular vaults.

HEMISPHERE, the half of a sphere or globe, when divided in two by a plane passing through its centre.

HEMISPHERE, in Astronomy, is particularly used for one half of the mundane sphere. The equator divides the sphere into two equal parts, called the northern and southern hemispheres. The horizon also divides the sphere into two equal parts, called the upper and lower hemispheres.

Hemisphere is also used for a map or projection of half the terrestrial globe, or of half the celestial sphere, on a plane; being more frequently called a planisphere. The centre of gravity of a hemisphere, is five-eighths of the radius distant from the vertex. A hemisphere unites the parallel rays at the distance of four-thirds of a diameter from the pole of the glass.

HEMISPHERES of *Magdeburgh*, two brass concave hemispheres, one of which is furnished with a cock, by which it may be adjusted to the air-pump. The other has a ring at the middle of its convexity, by means of which it may be suspended. When these two hemispheres are placed together, the air is drawn from within through the medium of the cock by the mechanism of the air-pump; and then, the exhaustion being carried far enough, and the cock turned to prevent the admission of air from without, a considerable force is requisite to separate the hemispheres; the force varying with their great circle. This furnishes an easy and obvious method of proving the pressure of the air. Otto Guericke, the inventor of the air-pump, to whom also is due this invention, made hemispheres of about a foot radius, and found that the atmospheric pressure on them was equivalent to about 5400 pounds.

HEMISPEROIDAL, in Geometry, something that approaches to the figure of a hemisphere, but is not justly so.

HEMITONE, in Music, a half note, or semi-tone.

HENDECAGON, a figure of eleven sides, or the E decagon; which see.

HENIOCHAS, or **HENIOCHUS**, a northern constellation, the same as Auriga, which see.

HEPTAGON, in Geometry, a figure of seven sides and seven angles.—When those sides and angles are all equal, the heptagon is said to be regular, otherwise it is irregular.—In a regular heptagon, the angle \angle at the centre is $= 51^{\circ} \frac{2}{7}$, the angle \angle DAB of the polygon is $= 128^{\circ} \frac{2}{7}$, and its half \angle CAB $= 64^{\circ} \frac{2}{7}$. Also the area is $=$ the square of the side $AB^2 \times 3\sqrt{6399124} = AB^2 \times \frac{1}{4}t^2$, where t is the tangent of the angle CAB of $64^{\circ} \frac{2}{7}$ to the radius 1; or t is the root of the equation;

$$t^{12} - 26t^{10} + 143t^8 - 245t^6 + 143t^4 - 26t^2 + 1 = 0;$$

$$t = \sqrt{\frac{1+x}{1-x}} = \frac{1+\sqrt{(1-y^2)}}{y} = \frac{y}{1-\sqrt{(1-y^2)}}$$

where the value of x and y are the roots of the equations

$$x^6 - \frac{5}{4}x^4 + \frac{3}{2}x^2 - \frac{1}{4}x = 0,$$

$$y^6 - \frac{7}{4}y^4 + \frac{3}{2}y^2 - \frac{1}{4}y = 0.$$

See my Mensuration, pa. 86, 4th edition.

HEPTAGON, in Fortification, a place fortified or strengthened with seven bastions for its defence.

HEPTAGONAL Numbers, are a kind of polygonal numbers in which the difference of the terms of the corresponding arithmetical progression is 5. Thus,

Arithmeticals, 1, 6, 11, 16, 21, 26, &c.

Heptagonals, 1, 7, 18, 34, 55, 81, &c.; where the heptagonals are formed by adding continually the terms of the arithmeticals, above them, whose common difference is 5.—One property, among many others, of these heptagonal numbers is, that if any one of them be multiplied by 40, and to the product be added 9, the sum will be a square number.

$$\text{Thus } 1 \times 40 + 9 = 49 = 7^2;$$

$$\text{and } 7 \times 40 + 9 = 289 = 17^2;$$

$$\text{and } 18 \times 40 + 9 = 729 = 27^2;$$

$$\text{and } 34 \times 40 + 9 = 1369 = 37^2; \text{ &c.}$$

Where it is remarkable that the series of squares so formed is $7^2, 17^2, 27^2, 37^2, \text{ &c.}$ the common difference of whose roots is 10, the double of the common difference of the arithmetical series, from which the heptagonals are formed.

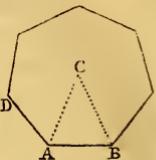

—See **POLYONALS**.

HEPTANGULAR Figure, in Geometry, is one that has seven angles; and therefore also seven sides.

HERCULES, in Astronomy, a constellation of the northern hemisphere, and one of the 48 old constellations mentioned by ancient writers. The stars in this constellation, in Ptolemy's catalogue, are 29; in Tycho's, 28; and in the Britannic catalogue, 113.

HERISSON, in Fortification, a beam armed with iron spikes, having their points turned outward. It is supported in the middle by a stake, having a pivot on which it turns; and serves as a barrier to block up a passage.—Herissons are frequently placed before gates, especially the posterns of a town or fortress, to secure those passages which must of necessity be often opened.

HERMANN (JAMES), a learned mathematician of the Academy of Berlin, and member of the Academy of Sciences at Paris, was born at Basil in 1678. He was a great traveller; and for 6 years was professor of mathematics at Padua. He afterwards went to Russia, being invited thi-

ther by the Czar in 1724, as well as his compatriot Daniel Bernoulli. On his return to his native country, he was appointed professor of morality and natural law at Basil; where he died in 1733, at 55 years of age. Hermann wrote several mathematical and philosophical pieces, in the Memoirs of different Academies, and elsewhere; but his principal work, is the *Phoronoma*, or two Books on the Forces and Motions of both Solid and Fluid Bodies; 4to, 1716: a very learned work on the new mathematical physics.

HERMETIC, or *HERMETICAL Art*, a name given to chemistry, on a supposition that Hermes Trismegistus was its inventor.

HERMETICAL Philosophy, is that which undertakes to solve and explain all the phenomena of nature, from the three chemical principles, salt, sulphur, and mercury. A considerable addition was made to the ancient hermetical philosophy, by the modern doctrine of alkali and acid.

HERMETICAL Seal, or *Hermetical Sealing*, a manner of stopping or closing glass vessels, for chemical and other operations, so very closely, that no substance can possibly exhale or escape. This is usually done by heating the neck of the vessel in the flame of a lamp, with a blow-pipe, till it be ready to melt, and then with a pair of hot pincers twisting it close together.

HERO, or **HERON**, the name of two celebrated mathematicians of the Alexandrian school, under Ptolemy Evergetes II; one called the elder, who wrote a very ingenious treatise on various pneumatics and hydraulic machines, translated into Latin, and published in several editions and forms, since the invention of printing; first a very elegant edition by Commandine, in 4to, 1583, entitled *Heronis Alexandrini Spiritualium Liber*. To this was added *Quatuor Thoremata Spiritalia*, by Joan. Bapt. Aleotti; translated from Italian into Latin; Amsterdam, 1680, in 4to. The other, called the younger, under the Emperor Heraclius, left a Treatise on Mechanics and Mensuration, published in Latin, at Venice, 1572, in 4to, entitled *Heronis Mechanici, liber de Machinis Bellicis, nec non liber de Geodæsia*. A Francisco Barocia, patritio Veneto latinitate donati, multis mendis expurgati, et figuris, ac scholiis illustrati.

HERSCHEL. See *URANUS*.

HERSCHEL's Telescope, a curious one made by that astronomer, being a reflecting one, and the largest ever constructed, 40 feet in length. The figure of it is exhibited in plate xv, and the description as follows, abridged from the Philos. Trans. vol. 85, or from my Abridg. vol. 17, pa. 593.

The telescope is placed in a situation due north and south, and the plate delineates the whole apparatus as seen by a person placed at a convenient distance from it towards the south-west. From this view the structure is sufficiently understood; and with very little attention, the mode of pointing this immense body to any part of the heavens, will be clearly seen. We shall treat of the chief parts in their order; and first, of the tube itself.

The tube is made of rolled or sheet iron, joined together without rivets, by a seaming similar to that which is used for iron funnels for stoves; the thickness of the sheets is somewhat less than a 36th part of an inch, or it may be found more accurately by taking a square foot of it at the weight of 14 pounds. Great care was taken in so joining together the plates, of which the tube is composed,

that the cylindrical form should be secured, and then the whole was coated over three or four times with paint, inside and outside, to secure it against the damp. The tube was formed at a short distance from its present place, and removed with great ease by 24 men, divided into six sets; so that two men on each side, with a pole of 5 feet long in their hands, to which was affixed a piece of coarse cloth, 7 feet long, going under the tube, and joined to a pole of 5 feet long, in the hands of two other men, assisted in carrying the tube. The length of the tube is 39 feet 4 inches, the diameter 4 feet 10 inches; and upon a moderate computation it is supposed that a wooden tube for the same purpose would have exceeded this in weight by at least 3000 pounds. The length of the iron plate forming the tube, and composed of smaller ones 3 feet 10 inches long, and 23½ inches broad; is nearly 40 feet, and the breadth 15 feet 4 inches.

The great mirror which, by proper methods, was brought to the lower part of the tube, is made of metal, 49½ inches in diameter; but the concave part, or polished surface, is only 48 inches in diameter. Its thickness is 3½ inches; and when it came from the cast, its weight was 2118 pounds, of which a small quantity must have been lost in polishing. An iron ring, 49½ inches in diameter within, 4 inches broad, and 1½ inch thick, with three strong handles to it, goes round the mirror, and a flat cover of tin is made to correspond with this ring, that the mirror may be preserved from damp; and, by an easy contrivance, it is taken off and fixed on at pleasure.

At the upper end the tube is open, and directed to the part of the heavens intended for observation, to which the observer's back is turned, and he, standing on the foot-board visible in the plate, looks down the tube, and perceives the object by rays reflected from the great mirror, through the eye-glass at the opening of the tube. Near the place of the eye-glass is the end of a tin pipe, into which a mouth-piece may be placed; so that, during an observation, a person may direct his voice into this pipe, while his eye is at the glass. This pipe is 1½ inch in diameter; runs down to the bottom of the tube, where it goes into a turning joint, thence into a drawing tube, and out of this into another turning joint, from which it proceeds by a set of sliding tubes towards the front of the foundation timber. The use of this tube is to convey the voice of the observer to his assistants; for at the last place it divides itself into two branches, one going into the observatory, the other into the workman's room, ascending into both places through the floor, and being terminated in the usual shape of speaking-trumpets. Though the voice passes in this manner through a tube with many inflections, and not less than 115 feet, it requires very little exertion to be well understood.

To direct so immense a body to any part of the heavens at pleasure, much ingenuity, and many mechanical contrivances are evidently necessary. The whole apparatus rests upon rollers, and care was previously taken of the foundation in the ground. This consists of concentrical circular brick walls, the outermost 42 feet, the innermost 21 feet in diameter; 2 feet 6 inches deep underground; 2 feet 3 inches broad at bottom, and 1 foot 2 inches at the top, capped with paving-stones, about 3 inches thick, and 12½ inches broad. In the centre is a large post of oak, framed together with braces underground, and walled fast with brick-work, to make it steady. Round this

centre, the whole frame is moved horizontally, by means of 20 rollers, 12 upon the outer, and 8 upon the inner wall.

The vertical motion is given to the telescope by means of ropes and pulleys as seen in the plate, passing over the main-beam, supported by the ladders. These ladders are in length 49 feet 2 inches; and there is a moveable gallery with 24 rollers to case its motion. The small staircase, visible in the plate, is intended for persons who wish to ascend into the gallery, without being obliged to go up the ladder. The ease with which the horizontal and vertical motions may be communicated to the tube, will be best conceived from a remark of Dr. Herschel's, that, in the year 1789, he several times observed Saturn two or three hours before and after its meridional passage, with one single person to continue, at his directions, the necessary horizontal and vertical motions.

Upon the platform are visible two rooms, the one called the Observatory, 8 feet 5 inches by 5 feet 5 inches, the other called the Working-room, 6 feet 6 inches by 4 feet 5 inches. To persons in these rooms, as has been above remarked, the observer can give his directions by means of the speaking-pipes; and in the rooms may be placed things commonly used in an observatory.

From a view of the plate and the description thus given of it, the reader will form a competent idea of an instrument, which, with proper eye-glasses, magnifies above 6000 times, and is the largest that has ever been made. Astronomers in different parts of the world may be discouraged from continuing their observations, when it should seem that their discoveries must be anticipated by our observer; but though he has so much the advantage, much is left to their labour and industry. It did not require a telescope of this magnitude to observe the object which was first discovered to be a planet by our astronomer, for it had been seen and taken for a fixed star by many persons in the two last centuries. And the double ring of Saturn, which has indeed been so beautifully observed through Herschel's magnifier, had been already described by Cassini in his Memoirs. Such of our readers as wish for a more particular account of this instrument will find it in the Transactions of the Royal Society for 1795, second part; in which there are 18 plates, and 63 pages of letter-press, to give an ample detail of every circumstance relating to joiner's work, carpenter's work, smith's work, &c: which has attended the formation and erection of this instrument. It was completed on August the 28th, 1789, on which day the sixth satellite of Saturn was discovered.

HERSE, in Fortification, a lattice or portcullice, in the form of a harrow, beset with iron spikes, to block up a gate-way, &c.

HERSILLON, or little Herse, in Fortification, is a plank armed with iron spikes, for the same use as the herse, and also to impede the march of the infantry or cavalry.

HERWART (JOHN GEORGE), chancellor of Bavaria at the beginning of the 17th century, was descended from a Patrician family of Augsburg. He was author of several curious books. 1. *Tabulae Arithmeticae Universales*, &c. Monach. Bavar. in large folio, 1610. This is perhaps a work of the most stupendous magnitude and labour in numeral calculations that ever was executed, consisting of a table of numbers closely printed on 999 large folio pages, for readily taking out the products and quotients of all numbers by inspection only; being in fact an

immense multiplication-table, of all factors or numbers, both up to 1000 each, or 1 million of products. Many examples of multiplications and divisions are prefixed, with applications to the calculations of spherical triangles. And, but for the more compendious invention of logarithms, which soon after took place, Herwart's tables would doubtless still have been in constant use for similar purposes.—2. Herwart also wrote an Apology for the Emperor Louis of Bavaria, against the falsehoods asserted by Bzovius.—3. *Chronologia, nova et vera*, 1612 and 1626, 2 parts, 4to.—4. Another very singular book, which was published by his son, John Frederick Herwart, entitled, *Admiranda ethicae Theologie Mysteria propulata, de antiquissima veterum Nationum Superstitione, &c;* 1624, 4to.

HESSE (WILLIAM Prince of), rendered his name immortal by his encouragement of learning, by his studies, and by his observations, for many years, of the celestial bodies. For this purpose, he erected an observatory at Cassel, and furnished it with good instruments, well adapted to that design; calling also to his assistance two eminent artists, Christopher Rothmann and Juste Bryce. His observations, which are of a very curious nature, were published at Leyden, in the year 1618, by Willebrord Snell; and are in part mentioned by Tycho Brahe, as well in his epistles as in the 2d volume of his *Progymnasmata*; a signal example to all princely and heroic minds, to undertake the promoting the arts of peace, and advancing this truly noble and celestial science. This prince died in the year 1597.

HETERODROMUS Vectis, or Lever, in Mechanics, a lever in which the fulcrum, or point of suspension is between the weight and the power; being the same as what is otherwise called a lever of the first kind.

HETEROGENEOUS, or HETEROGENEAL, literally imports things of different natures, or something that consists of parts of different or dissimilar kinds; in opposition to Homogeneous. Thus,

HETEROGENEOUS Bodies, are such as have their parts of unequal density.

HETEROGENEOUS Light, that which consists of parts or rays of different refrangibility, reflexivity, and colour. Thus, the common light of the sun, or clouds, is heterogeneous, being a mixture of all sorts of rays.

HETEROGENEOUS Numbers, are mixed numbers, consisting of integers and fractions.

HETEROGENEOUS Particles, are such as are of different kinds, natures, and qualities; of which generally all bodies consist.

HETEROGENEOUS Quantities, in Mathematics, are those which cannot have proportion, or be compared together as to greater and less; being of such different kind and consideration, as that one of them taken any number of times, never equals or exceeds the other. As lines, surfaces, and solids in geometry.

HETEROGENEOUS Surds, are such as have different radical signs, as \sqrt{a} and $\sqrt{b^2}$; or $\sqrt{10}$ and $\sqrt{20}$.

HETEROSCHI, in Geography, are such inhabitants of the earth as have their shadows at noon projected always the same way with regard to themselves, or always contrary ways with respect to each other. Thus, all the inhabitants without the torrid zone are Heteroschi, with regard to themselves, since any one such inhabitant has his shadow at noon always the same way, viz, always north of him in north latitude, and always south of him in south

latitude; or these two situations are Heteroscii to each other, having such shadows projected contrary ways at all times of the year.

HEVELIUS (JOHN), a very celebrated astronomer, and a burgomaster of Dantzick, was born in that city in 1611. He studied mathematics under Peter Cruger, in which he made a wonderful progress. He afterwards spent several years on his travels through Holland, England, Germany, and France, for his improvement in the sciences. On his return, he constructed excellent telescopes himself, and began diligently to observe the heavens, an employment he closely followed during the course of a long life, which was terminated only in 1687, at 76 years of age. Hevelius was author of several remarkable discoveries in the heavens. He was the first who observed the phenomenon called the libration of the moon, and made several other important observations on the other planets. He also discovered several fixed stars, which he named the Firmament of Sobieski, in honour of John the 3d, king of Poland. He also framed a large catalogue of the stars, and collected multitudes of the unformed ones into new constellations. His wife was also well skilled in astronomy, and made a part of the observations that were published by her husband. Our author's principal publications are, his *Selenographia*, or an exact description of the moon ; in which he has engraved all her phases, and remarkable parts, distinguished by names, and ascertained their respective bounds by the help of telescopes ; containing also a delineation of the several visible spots, with the various motions, changes, and appearances, discovered by the telescope, as also in the sun and other planets, 1647.—In 1654, two epistles ; one to the celebrated astronomer Riccioli, concerning the Libration of the Moon ; and the other to Bulliald, on the Eclipses of both luminaries.—In 1656, a Dissertation, *De Natura Saturni faciei*, &c.—In 1668, his *Cometographia*, representing the whole nature of comets, their situation, parallaxes, distances, diverse appearances, and surprising motions, with a history of all the comets from the beginning of the world down to the present time ; being enriched with curious sculpture of his own execution : to which he added a treatise on the planet Mercury, seen in the sun at Dantzick, May 3, 1661 ; with the history of a new star appearing in the neck of Cetus, and another in the beak of Cygnus ; besides an illustration of some astronomical discoveries of the late Mr. Horrox, in his treatise on Venus seen in the sun, November 24, 1639 ; with a discourse of some curious Parasele and Parhelion observed at Dantzick. He sent copies of this work to several members of the Royal Society at London, and among them to Mr. Hooke, in return for which, this gentleman sent to Hevelius a description of the Dioptric Telescope, with an account of the manner of using it ; and recommending it to him, as much preferable to telescopes with plain sights. This gave rise to a dispute between them, *viz.*, "whether distances and altitudes could be taken with plain sights any nearer than to a minute." Hooke asserted that they could not ; but that, with an instrument of a span radius, by the help of a telescope, they might be determined to the exactness of a second. Hevelius, on the other hand, insisted that, by the advantage of a good eye and long practice, he was able with his instruments to come up even to that exactness ; and, appealing to experience and facts, sent by way of challenge 8 distances, each between two different stars, to be examined by Hooke. Thus the affair rested for some time with out-

ward decency, but not without some inward grudge between the parties.

In 1673, Hevelius published the first part of his *Machina Coelestis*, as a specimen of the exactness both of his instruments and observations ; and sent several copies as presents to his friends in England, but omitting Mr. Hooke. This, it is supposed, occasioned that gentleman to print, in 1674, *Animadversions on the First Part of the Machina Coelestis* ; in which he treated Hevelius with a very magisterial air, and threw out several unhandsome reflexions, which were greatly resented. This was the cause of a most violent dispute, which arose afterwards to such a height, and became so notorious, that in 1679 Dr. Halley went, at the request of the Royal Society, to examine both the instruments and the observations made with them. Of both these, Halley gave a favourable account, in a letter to Hevelius ; and Hooke managed the controversy so ill, that he was universally condemned, though the preference has since been given to telescopic sights. However, Hevelius could not be prevailed on to make use of them : whether he thought himself too experienced to be informed by a young astronomer, as he considered Hooke ; or whether, having made so many observations with plain sights, he was unwilling to alter his method, lest he might bring their exactness into question ; or whether, being by long practice accustomed to the use of them, and not thoroughly apprehending the use of the other, nor well understanding the difference, is uncertain. Besides Halley's letter, Hevelius received many others in his favour, which he took the opportunity of inserting among the astronomical observations in his *Annus Climactericus*, printed in 1685. In a long preface to this work, he speaks with more confidence and greater indignation than he had done before, and particularly exclaimed against Hooke's dogmatical and magisterial manner of assuming a kind of dictatorship over him. This revived the contest, and excited so much interest as to occasion several other learned men to engage in it. The book itself being sent to the Royal Society, at their request an account of it was given by Dr. Wallis ; who, among other things, took notice, that, "Hevelius's observations had been misrepresented, since it appeared from this book, that he could distinguish by plain sights to a small part of a minute." About the same time Mr. Molyneux also wrote a letter to the Society, in vindication of Hevelius, against Hooke's animadversions. To all which, Hooke drew up a letter in answer, which was read before the society, containing many qualifying and accommodating expressions, but still at least expressing the superiority of telescopic sights over plain ones, excellent as the observations were that had been made with these.

Hevelius had published in 1679, the second part of his *Machina Coelestis* ; but the same year, while he was at a seat in the country, he had the misfortune to have his house at Dantzick burnt down. By this calamity it is said he sustained several thousand pounds damage ; having not only his observatory and all his valuable instruments and astronomical apparatus destroyed, but also a great many copies of his *Machina Coelestis*, an accident which has made this second part very scarce.

In 1690, were published a description of the heavens, called, *Firmamentum Sobiescianum*, in honour of John the 3d, king of Poland, as above mentioned ; and also *Prodromus Astronomiae, et Novae Tabulae Solares*, una cum Catalogo Fixarum ; in which are contained the necessary preliminaries for taking an exact catalogue of the stars.

Both these works were posthumous; for Hevelius died the 28th of January 1657, exactly 76 years of age, as before observed, and universally admired and respected; abundant evidence of which appears in a collection of letters between him and many other persons, that was printed at Dantzig in 1683.

HEURAET (VAN), a respectable Dutch mathematician. He contributed some pieces on the nature of equations, in the commentaries published by Schoeten, on the geometry of Descartes; and, by pursuing the analyses of that author, recommended himself to notice by his invention for rectifying the curve of the semicubical parabola. In this, however, he was anticipated by the English mathematician Neil, who had some years before discovered the rectification of that curve. But it is very probable that Van Heuraet knew nothing of Neil's discovery; and besides, the two methods are very different from each other.

HEXACHORD, a certain interval or musical concord, usually called a sixth.

HEXAEDRON, or **HEXAEDRON**, one of the five regular or of Platonic bodies; being indeed the same as the cube; and is so called from its having 6 faces.—The square of the side or edge of a hexahedron, is one-third of the square of the diameter of the circumscribing sphere: and hence the diameter of a sphere is to the side of its inscribed hexahedron, as $\sqrt{3}$ to 1.

In general, if a , b , and c be put to denote respectively the linear side, the surface, and the solidity of a hexahedron or cube, also r the radius of the inscribed sphere, and R the radius of the circumscribed one; then we have these general equations or relations :

$$\begin{aligned} 1. \quad a &= 2r = \frac{2}{\sqrt{3}}r\sqrt{3} = \sqrt{\frac{1}{6}B} = \sqrt[3]{c}. \\ 2. \quad B &= 24r^2 = 8r^2 = 6A^2 = 6\sqrt[3]{c^2}. \\ 3. \quad c &= 8r^3 = \frac{8}{\sqrt{3}}r^3\sqrt{3} = A^3 = \frac{1}{6}B\sqrt{\frac{1}{6}B}. \\ 4'. \quad R &= r\sqrt{3} = \frac{1}{2}A\sqrt{3} = \frac{1}{2}\sqrt{\frac{1}{6}B} = \frac{1}{2}\sqrt{3} \times \sqrt[3]{c}. \\ 5. \quad r &= \frac{1}{2}R\sqrt{3} = \frac{1}{2}A = \frac{1}{2}\sqrt{\frac{1}{6}B} = \sqrt[3]{c}. \end{aligned}$$

HEXAGON, in Geometry, a figure of six sides, and consequently of as many angles. When these are equal, it is a regular hexagon.—The angles of a hexagon are each equal to 120° , and its sides are each equal to the radius of its circumscribing circle. Hence a regular hexagon is inscribed in a circle, by applying the radius 6 times successively to the periphery, and joining with right lines the several divisions. And hence also, to describe a regular hexagon upon a given line, describe an equilateral triangle upon it, the vertex of which will be the centre of the circumscribing circle.

The side of a hexagon being s , its area will be $= 2.5980762s^2 = \frac{3}{2}s^2 \times \tan 60^\circ = \frac{3}{2}s^2\sqrt{3}$.

HEXAGON, in Fortification, is a six-lined figure defended by six bastions.

HEXASTYLE, in the Ancient Architecture, a building with 6 columns in front.

HIERO'S CROWN, in Hydrostatics. The history of this crown, and of the important hydrostatical proposition which it gave occasion to, is as follows: Hiero, king of Syracuse, having furnished a workman with a quantity of

gold for making a crown, suspected that he had been cheated, by the workman using a greater alloy of silver than was necessary in making it; and he applied to Archimedes to discover the fraud, without defacing the crown.

This celebrated mathematician was led by chance to a method of detecting the imposture, and of determining precisely the quantities of gold and silver composing the crown: for he observed, when bathing in a tub of water, that the water ran over as his body entered it, and he presently concluded that the quantity so running over was equal to the bulk of his body that was immersed. He was so pleased with the discovery, that it is said he ran about naked, crying out, *εὕρηκα, εὕρηκα, I have found it;* and some affirm that he offered a hecatomb to Jupiter for having inspired him with the thought.

On this principle he procured a ball or mass of gold, and another of silver, exactly of the same weight with the crown; considering, that, if the crown were of pure gold, it would be of equal bulk, and expel an equal quantity of water as the golden ball; and if it were of silver, then it would be of equal bulk and expel an equal quantity of water with the ball of silver; but of intermediate quantity, if it consisted of a mixture of the two, gold and silver. This, upon trial, he found to be the case; and hence, by a comparison of the quantities of water displaced by the three masses, he determined the exact portions of gold and silver in the crown.

Now suppose, for example, that each of the three masses weighed 100 ounces; and that on immersing them severally in water, there were displaced 5 ounces of water by the golden ball, 9 ounces by the silver, and 6 ounces by the compound, or crown; that is, their respective or comparative bulks are as 5, 9, and 6, the sum of which is 20.

Then the method of operation is this:

From	9	6
Take	6	5
rem.	3	1,

whose sum is 4.
Therefore 4 : 100 :: 3 : 75 oz. of gold,
and 4 : 100 :: 1 : 25 oz. of silver.

That is, the crown consisted of 75 ounces of gold, and 25 ounces of silver.

See Cotes Hydros. Lect. p. 81; or Martin's Philos. Britan. vol. 1, p. 305, &c. See also SPECIFIC Gravity.

HIGH-WATER, that state of the tides when they have flowed to their greatest height, or have ceased to flow or rise. At high-water the motion commonly ceases for a quarter or half an hour, before it begins to ebb again. The times of high-water of every day of the moon's age, is usually computed from that which is observed on the day of the full or change; viz, by taking 4-5ths of the moon's age on any day of the month, and adding it to the time of high-water on the day of the full or change; then is the sun nearly equal to the time of high-water on the day of the month proposed. And as to the times of high-water, on the day of the full and change of the moon, at many different places; they have been observed as they are set down in the following table.

TABLE of the Times of High-water on the Days of the New and Full Moons, at many different Places.

HIPS, in Architecture, are those pieces of timber placed at the corners of a roof. These are much longer than the rafters, because of their oblique position.

HIP means also the angle formed by two parts of the roof, when it rises outwards.

HIP-Roof, called also Italian Roof, is one in which two parts of the roof meet in an angle, rising outwards : the same angle being called a valley when it sinks inwards.

HIPPARCHUS, a celebrated ancient astronomer, was born at Nice in Bithynia, and flourished between the 154th and the 163d Olympiads ; that is, between 160 and 135 years before Christ ; for in this interval of time it is that his observations are dated. He is accounted the first, who from vague and scattered observations reduced astronomy into a science, and prosecuted the study of it systematically. Pliny often mentions him, and always with great commendation. He was the first, he tells us, who attempted to count the number of the fixed stars ; and his catalogue is preserved in Ptolemy's Almagest, where they are all noted according to their longitudes and apparent magnitudes. The same author places him among those men of a sublime genius, who, by foretelling the eclipses, taught mankind, that they ought not to be alarmed at these phenomena. Thales was the first among the Greeks, who could discover when there was to be an eclipse. Sulpitius Gallus among the Romans began to succeed in this kind of prediction ; and he gave an essay of his skill very opportunely, the day before a battle was fought. After these, Hipparchus improved the science of eclipses very considerably : making ephemerides, or catalogues of eclipses, for 600 years. Pliny admires him for making a review of all the stars, acquainting us with their situations and magnitudes ; for by these means, observes he, posterity will be able to discover, not only whether

they are born and die, but also whether they change their places, and whether they increase or decrease. He mentions also a new star which was produced in his days ; and that by its motion, when it first appeared, he began to doubt whether this did not frequently happen, and whether those stars, which we call fixed, do not likewise move. Hipparchus is also memorable for being the first who discovered the precession of the equinoxes, or a very slow apparent motion of the fixed stars from east to west, by which in a great number of years they will appear to have performed a complete revolution. He endeavoured also to reduce to rule the many discoveries he made, and invented new instruments, by which he marked their magnitudes and places in the heavens : so that by means of them it might be easily observed, not only whether they appear and disappear, but also whether they pass each other, or move, and whether they increase or decrease.

The first observations made by Hipparchus, were in the isle of Rhodes ; whence he got the name Rhodius ; but afterwards he cultivated this science in Bithynia and Alexandria only. One of his works is still extant, viz. his Commentary on Aratus's Phenomena. He composed several other works ; and on the whole it is agreed, that astronomy is greatly indebted to him, for laying that rational and solid foundation, on which all succeeding astronomers have built their superstructure.

HIPPOCRATES, of Chios, a respectable Greek geometrician, but originally it seems a merchant, who, from his honest and unsuspecting simplicity of nature, being greatly imposed on, and half ruined by the knavery of the farmers of the revenue at Byzantium (now Constantinople), suspended his commerce, and repaired to Athens to retrieve his affairs, where he first became acquainted with geometry. Curiosity, or amusement, having one day

led him to visit one of the schools of philosophy, he so much relished the lectures on geometry, which he there heard, that he resolved to devote himself to the study of that science. He soon became a distinguished geometri-cian. The quadrature of the lunes, which he discovered, emboldened him to attempt also that of the circle. He also composed Elements of Geometry, which have not however reached our times.

HIRCUS, in Astronomy, a fixed star of the first magnitude, the same with Capella.

HIRCUS is also used by some writers for a comet, encompassed as it were with a mane, seemingly rough and hairy.

HIRE (PHILIP DE LA), an eminent French mathematician and astronomer, was born at Paris in 1640. His father, who was paitor to the king, intending him for the same occupation, taught him drawing and such branches of mathematics as relate to it: but died when the son was only 17 years of age. Three years after this, he travelled into Italy for improvement in that art, where he spent 4 years. He applied himself also to mathematics, which at last engrossed all his attention. On his return to Paris, he continued his mathematical studies with great eagerness, and afterwards published some works, which gained him so much reputation, that in 1678 he was named a member of the Academy of Sciences.

Colbert the minister having formed a design for a better chart or map of France than any which had then been conceived, Lahire was appointed, with Picard, to make the necessary observations for that purpose. This occupied him some years in several of the provinces; and was the main object of his peregrinations. But he was not, however, unmindful of other branches of knowledge, for he philosophized on every thing that occurred, and particularly on the phenomena of the variations of the magnetic needle, and refractions, as also on the height of mountains, as determined by the barometer.

In 1683, Lahire was employed in continuing the meridian line, which, Picard had begun in 1669. He continued it from Paris northward, while Cassini carried it on to the south; but Colbert dying the same year, the work was relinquished before it was finished. Lahire was next employed, with other members of the Academy, in taking the necessary levels for the grand aqueducts which Louis the 14th was about to make.

The great number of works published by our author, together with his continual employments, as professor of the Royal College and of the Academy of Architecture, give us some idea of the great labours he underwent. His days were always spent in study: his nights very often in astronomical observations; seldom seeking any other relief from his labours, than a change of one for another. In his manner, he had the exterior politeness, circumspection, and prudence of Italy; on which account he appeared too reserved in the eyes of his countrymen; though he was always esteemed as a very honest disinterested man. He died in 1718, at 78 years of age.

Of the numerous works which he published, the principal are, 1. *Traité de Méchanique*; 1665.—2. *Nouvelle Méthode en Géométrie pour les Sections des Superficies Coniques et Cylindriques*; 1673, 4to.—3. *De Cycloïde*; 1677, 12mo.—4. *Nouveaux Éléments des Sections Coniques: les Lieux Géométriques: la Construction, ou Effectuation des Equations*; 1678, 12mo.—5. *La Gnomonique, &c.*; 1682, 12mo.—6. *Traité du Nivellement de M. Pi-*

card, avec des additions; 1684.—7. *Sectiones Conicæ in novem libros distributa*; 1685, folio. This was considered as an original work, and gained the author great reputation all over Europe.—8. *Traité du Mouvement des Eaux, &c.*; 1686.—9. *Tabulae Astronomicæ*; 1687 and 1702, 4to.—10. *Ecole des Arpenteurs*; 1689.—11. *Veterum Mathematicorum Opera, Græcæ et Latinæ, placa-que nunc primum edita*; 1693, folio. This edition had been begun by Thevenot; who dying, the care of finishing it was committed to Lahire. It shows that our author's strong application to mathematical and astronomical studies had not hindered him from acquiring a very competent knowledge of the Greek tongue. Besides these, and other smaller works, a vast number of his pieces are diffused in Journals, and particularly in the *Mémoirs of the Academy of Sciences*, viz, from 1666 till the year 1718.

HOBBS (THOMAS), a famous writer and philosopher, was born at Malmesbury in Wiltshire, in 1588, being the son of a clergyman of that place. He completed his studies at Oxford, and was afterwards governor to the eldest son of William Cavendish earl of Devonshire, with whom he travelled through France and Italy, applying himself closely to the study of polite literature. In 1626 his patron the earl of Devonshire died; and in 1628 his son also; the same year Mr. Hobbes published his translation of Thucydides in English. He soon after went abroad a second time as governor to the son of Sir Gervase Clifton; but shortly after returned, to resume his concern for the hopes of the Devonshire family, to whom he had so early attached himself; the countess-dowager having desired to put the young earl under his care, then about 13 years of age. This charge was very agreeable to Mr. Hobbes's inclinations, and he discharged the trust with great diligence and fidelity. In 1634 he accompanied his young pupil to Paris, where he employed his own vacant hours in the study of natural philosophy, frequently conversing with Father Mersenne, a man of great and deserved renown, and who corresponded with almost all the learned in Europe. From Paris he attended his pupil into Italy, where he became acquainted with the celebrated Galileo, who freely communicated his notions to him; and from hence he returned with his ward to England. But afterwards, foreseeing the civil wars, he went to seek a retreat at Paris; where he soon became acquainted with Descartes, with whom he afterwards held a correspondence on several mathematical subjects, as appears from the letters of Mr. Hobbes published in the works of Descartes.

But when this philosopher printed afterwards his *Meditations*, wherein he attempted to establish points of the highest consequence from innate ideas, Mr. Hobbes took the liberty of dissenting from him, as did also the French king's mathematical professor, the illustrious Peter Gassendi, with whom Mr. Hobbes contracted a very close friendship, which was not interrupted till the death of the former.

In 1642, Mr. Hobbes printed his famous book *De Cive*, which raised him many adversaries, who charged him with instilling principles of a dangerous tendency. Among many illustrious persons who, from the troubles in England, retired to France for safety, was Sir Charles Cavendish, brother to the duke of Newcastle; and this gentleman, being well skilled in the mathematics, proved a constant friend and patron to our author; who, by embarking in 1645 in a controversy about squaring the circle,

was become so famous by it, that in 1647 he was recommended to instruct Charles prince of Wales, afterwards King Charles the 2d, in mathematical learning. During this he employed his vacant time in composing his Leviathan, which was published in England in 1651. After the publication of this work, he returned to England, and passed the remainder of his long life in a very retired and studious manner, in the house of the earl of Devonshire, mostly at his seat in Derbyshire, but accompanying the earl always to London, fearing to be left out of his immediate protection, lest he should be seized by officers from the parliament or government, on account of the freedom of his opinions in politics and religion. He received great marks of respect from King Charles the 2d at the restoration in 1660, with a pension of 100l. a year. From that time, till his death, he applied himself to his studies, and in opposing the attacks of his adversaries, who were very numerous: in mathematical subjects, disputes rose to a great height between him and Dr. Wallis, on account of his pretended Quadrature of the Circle, Cubature of the Sphere, and Duplication of the Cube, which he obstinately defended without ever acknowledging his error.

His long life was that of a perfectly honest man; a lover of his country, a good friend, charitable and obliging. He accustomed himself much more to thinking than reading; and was fond of a well-selected, rather than a large library. He had a hatred to the clergy, having been persecuted by them on account of the freedom of his doctrine, and having a very indifferent opinion of their knowledge and their principles. In his last sickness he was very anxious to know whether his disease was curable; and when intimations were given, that he might have ease, but no remedy, he said, 'I shall be glad to find a hole to creep out of the world at.' He died the 4th of Dec. 1679, at 91 years of age.

His chief publications were,

1. An English translation of Thucydides's History of the Grecian War.—2. De Mirabilibus Pecci, and Memoirs of his own Life, both in Latin verse.—3. Elements of Philosophy.—4. Answer to Sir William Davenant's Epistle, or Preface to Gondibert.—5. Human Nature, or the Fundamental Elements of Policy.—6. Elements of Law.—7. Leviathan; or the Matter, Form, and Power of a Commonwealth.—8. A Compendium of Aristotle's Rhetoric.—9. A Letter on Liberty and Necessity.—10. The Questions, concerning Necessity and Chance, stated.—11. Six Lessons to the Professors of Mathematics, of the Institution of Sir Henry Saville.—12. The Marks of Absurd Geometry, &c.—13. Dialogues of Natural Philosophy.—Besides many other pieces on polity, theology, mathematics, and other miscellaneous subjects, to the number of 41.

HOBITS, in Gunnery. See HOWITZ.

HODGSON (JAMES), F. R. S. was a respectable mathematician in the early part of the 18th century, and some time master of the Royal Mathematical School in Christ's Hospital, London. Besides a multitude of papers in the Philos. Trans. from vol. 24 (anno 1704), to vol. 49 inclusive, he was also author of several mathematical works: as, 1. Treatise on Navigation, in 4to, 1706; 2. System of Mathematics, in 2 vols. 4to, 1723; 3. The Theory of Jupiter's Satellites, 4to, 1750; 4. The Doctrine of Fluxions, 4to, 1758: 5. The Valuation of Annuities upon Lives, 4to; 6. An Introduction to Chronology. And perhaps some others.—Mr. Hodgson was born 1672; elected F. R. S. 1703; and died June 25, 1755.

HOGSHEAD, a measure, or vessel, of wine or oil; containing the 4th part of a tun, the half of a pipe, or 63 gallons.

HOLDER (WILLIAM), a learned and philosophical Englishman, was born in Nottinghamshire, educated at Cambridge, and in 1642 became rector of Blechingdon in Oxfordshire. In 1660 he proceeded D. D., and became afterwards canon of Ely, fellow of the Royal Society, canon of St. Paul's, sub-dean of the royal chapel, and sub-almoner to the king. He was a general scholar, a very accomplished person, and a great virtuoso.—Dr. Holder greatly distinguished himself, by giving speech to a young gentleman of the name of Popham, who was born deaf. This was effected at his own house at Blechingdon in 1659; but the young man losing what he had been taught by Holder after he was called home to his friends, he was sent to Dr. Wallis, who brought him to his speech again. Holder published a book, entitled The Elements of Speech; an essay or inquiry into the natural Production of Letters: with an appendix, concerning persons that are deaf and dumb, 1669, 8vo. In the appendix he relates how soon, and by what methods, he brought young Popham to speak. In the Philos. Trans. for July 1670, was inserted a letter from Dr. Wallis, in which he claims to himself the honour of bringing that gentleman to speak. By way of answer to which, in 1678, Dr. Holder published, in 4to, A Supplement to the Philos. Trans. of July 1670, with some reflections on Dr. Wallis's letter there inserted. Upon which the latter soon after published A Defence of the Royal Society, and the Philos. Trans. particularly those of July 1670, in answer to the cavils of Dr. William Holder, 1678, 4to.

Dr. Holder's accomplishments were very general. He was skilled in the theory and practice of music, and wrote A Treatise of the Natural Grounds and Principles of Harmony, 1694, 8vo. He wrote also A Treatise concerning Time, with applications of the Natural Day, Lunar Month, and Solar Year, &c, 1694, 8vo. He died at Amen Corner in London, Jan. 24, 1697, and was buried in St. Paul's.

HOLLOW, in Architecture, a concave moulding, about a quarter of a circle, by some called a casement, by others an abacus.

HOLLOW-TOWER, in Fortification, is a rounding made of the remainder of two brisures, to join the curtain to the crillon, where the small shot are played, that they may not be so much exposed to the view of the enemy.

HOLY Thursday, otherwise called Ascension-day, being the 39th day after Easter Sunday, and kept in commemoration of Christ's ascension into heaven.

HOLY Rood, or Holy Cross, a festival kept on the 14th of September, in memory of the exaltation of the holy cross.

HOLY Week, is the last week of Lent, called also Passion week.

HOLYWOOD (JOHN), or HALIFAX, or Sacrobosco, an eminent mathematician of the 12th century, whose birthplace is variously ascribed. According to Leland, Bale, and Pitts, he was born at Halifax in Yorkshire: according to Stanhurst, at Holywood near Dublin; and according to Dempster and Mackenzie, in Nithsdale in Scotland: though it is possible there might have been more than one of the name. Mackenzie, however, informs us, that having finished his studies, he entered into orders, and became a canon regular of the order of St. Augustin

in the famous monastery of Holywood in Nithsdale. The English biographers, on the contrary, inform us that he was educated at Oxford. They all agree however in asserting, that he spent most of his life at Paris; where, observes Mackenzie, he was admitted a member of the university, June 5, 1221, under the syndics of the Scotch nation; and soon after was elected professor of mathematics, which he taught with applause for many years. According to the same author, he died in 1256, as appears from the inscription on his monument in the cloisters of the convent of St. Maturine at Paris.

Holywood was contemporary with Roger Bacon, but probably older by about 20 years. He wrote, 1. De Sphaera Mundi; a work often reprinted, and illustrated by various commentators.—2. De Anni Ratione, seu de Compute Ecclesiastico.—3. De Algorismo, printed with Comm. Petri Cirvilli Hisp : Paris, 1498. The Algorismus was probably the treatise, in technical verses, which he composed on the Arabian arithmetic.

HOMOCENTRIC, the same as Concentric.

HOMOCENTRIC, the same as Concentric.
HOMODROMUS *Vectis*, or *Lever*, in Mechanics, is a lever in which the weight and power are both on the same side of the fulcrum, as in the lever of the 2d and 3d kind; being so called because here the weight and power move both in the same direction, whereas in the Heterodromus they move in opposite directions.

HOMOGENEAL, or **HOMOGENEOUS**, consisting of similar parts, or of the same kind and nature, in contradistinction from **Heterogeneous**, where the parts are of different kinds.—Natural bodies are usually composed of homogeneous parts, as a diamond, a metal, &c. But artificial bodies, on the contrary, are assemblages of heterogeneous parts, or parts of different kinds; as a building, of stone, wood, &c.

HOMOGENEAL Light, is that whose rays are all of one and the same colour, refrangibility, &c.

HOMOGENEOUS Numbers, are those of the same kind and nature.

HOMOGENEAL Surds, are such as have one common radical sign; as $\sqrt{27}$ and $\sqrt{30}$, or \sqrt{a} and \sqrt{b} , or $2\sqrt[3]{c}$ and $\sqrt[3]{d}$.

HOMOGENEOUS Equations, in the doctrine of Fluxions, particularly treated by John Bernoulli, for integrating such forms of two fluxions of the first order, in which the sum of the dimensions of x and y , which affect \dot{x} and \dot{y} , rise to the same degree in all the terms, then the indeterminates may be separated by a simple substitution, as of yz for x : such for example as the fluxional equations

$$(ax^2 + xy)\dot{x} = (by^2 + x^2)\dot{y}, \text{ or } \frac{(ax + y)\dot{x}}{(by + x)\dot{y}} = \frac{by}{ax + x^2 - by^2}.$$

Then substituting, in the former of these, y_2 for x , and the fluxion of this for \dot{x} , by reduction the equation becomes

$$\frac{\dot{y}}{y} = \frac{az^2 + z}{b - az^2},$$
where the indeterminates are separated, and the fluents may be found.

In like manner the application is made to such homogeneous equations as the following:

$$\begin{aligned} & \text{General equations as the following:} \\ & (ax + by)\dot{x} + (cx + dy)\dot{y} = 0, \\ & (ax^2 + bxy + cy^2)\dot{x} + (dx^2 + exy + fy^2)\dot{y} = 0, \\ & (ax^3 + bx^2y + cxy^2 + dy^3)\dot{x} + (ex^2 + fx^2y + gxy^2 + hy^3)\dot{y} = 0 \\ & \quad \ddots \quad \ddots \end{aligned}$$

HOMOGENEUM *Adfectionis*, a name given by Vieta to the second term of a compound or affected equation, being that which makes it affected.

HOMOGENEUM *Comparationis*, in Algebra, a name

given by Vieta to the absolute known number or term in a compound or affected equation. This he places on the right-hand side of the equation, and all the other terms on the left.

HOMOLOGOUS, in Geometry, is applied to the corresponding sides of similar figures, or those that are opposite to equal or corresponding angles, and are so called because they are proportional to each other. — For all similar figures have their like sides homologous, or proportional to one another, also their areas or surfaces are homologous, or proportional to the squares of the like sides, and their solid contents homologous, or proportional to the cubes of the same.

HOOF, or *Ungula*, in Geometry, is a part cut off a cylinder, or cone, &c., by a plane passing both through the base and part of the curve surface. It has obtained its name from its resemblance to the hoof (*ungula*) of a horse. For the contents and surfaces of such hoofs, see my Mensuration, pa. 161—183, 4th edit.

With respect to the surfaces of conic unguis formed by planes perpendicular to the base, Father Guido Grandi first remarked, that if a polygon be inscribed in the base of a cone, and if on each side of this polygon a plane be raised perpendicular to the base, the portion of the conical surface cut off towards the axis, is equal to a rectilinear space. The portions also of the cone cut off by the above planes, towards the base, are in the same ratio as the segments of the base on which they stand. Indeed, whatever figure be inscribed in the base, if we conceive a right prismatic surface raised from the perimeter of the figure, it will cut off from the conical surface a portion, which will be to it in the same ratio, viz., that of the radius of the base to the slant height of the cone.

HOKE (ROBERT), a very celebrated mathematician and philosopher, was born, 1635, at Freshwater in the Isle of Wight, where his father was minister. He was intended for the church; but being of a weakly constitution, and very subject to the head-ach, all thoughts of that nature were laid aside. Thus left to himself, the boy followed the bent of his genius, which was turned to mechanics; and employed his time in making little toys, which he executed with wonderful art and dexterity. He had also a good turn for drawing; for which reason, after his father's death, which happened in 1648, he was placed with Sir Peter Lely; but the smell of the oil-colours increasing his head-ach, he quitted painting in a very short time. He was afterwards kindly taken by Dr. Busby into his house, and supported there, while he attended Westminster-school; where he not only acquired a competent share of Greek and Latin, together with an insight into Hebrew and some other Oriental languages, but also made himself master of a good part of Euclid's Elements; and, as Wood asserts, invented 30 different ways of flying.

About the year 1653 he went to Christ-church, Oxford; and in 1655 was introduced to the Philosophical Society there; where, discovering his mechanic genius, he was first employed to assist Dr. Willis in his chemical operations, and was afterwards recommended to Mr. Robert Boyle, whom he served several years in the same capacity. He was also instructed in astronomy about this time by Dr. Seth Ward, Savilian professor of that science; and henceforward distinguished himself by many noble inventions and improvements of the mechanical kind. He also invented several astronomical instruments, for making observations both at sea and land, and was particularly

serviceable to Mr. Boyle in completing the invention of the air-pump. In 1662 he was appointed Curator of Experiments to the Royal Society; and when that body was established by royal charter, he was in the list of those who were first named by the council in May 20, 1663; and was admitted accordingly June 3, with a peculiar exemption from all payments. Sept. 28 of the same year, he was named by Lord Clarendon, chancellor of Oxford, for the degree of M.A.; and Oct. 19 it was ordered that the repository of the Royal Society should be committed to his care; the white gallery in Gresham-college being appropriated to that use. In May 1664, he began to read the astronomy lecture at Gresham-college, for the professor Dr. Pope, then in Italy; and the same year he was made professor of mechanics to the Royal Society by Sir John Cutler, with a salary of 50*l.* per annum, which that gentleman, the founder, settled upon him for life. Jan. 11, 1665, that society granted a salary also of 30*l.* a year, for his office of curator of experiments for life; and the month of March the same year he was elected professor of geometry in Gresham-college.

In 1665 he published in folio, his Micrographia, or some Philosophical Descriptions of Minute Bodies, made by Magnifying Glasses, with Observations and Inquiries on them. And the same year, during the recess of the Royal Society on account of the plague, he attended Dr. Wilkins and other ingenious gentlemen into Surrey, where they made several experiments. In 1666 he produced to the Royal Society a model for rebuilding the city of London, then destroyed by the great fire, with which the society was well pleased; and the lord mayor and aldermen preferred it to that of the city surveyor, though it happened not to be carried into execution. The rebuilding of the city, according to the act of parliament, requiring able persons to set out the ground for the proprietors, Mr. Hooke was appointed one of the surveyors; an employment in which he acquired most part of his estate, as appeared from a large iron chest of money found after his death, locked down with a key in it, and a date of the time, which showed it to have been so shut up above 30 years. From 1668 he was engaged for many years in a warm contest with Hevelius, concerning the difference in accuracy between observing with astronomical instruments with plain and telescopic sights; in which dispute many learned men afterwards engaged, and in which Hooke managed so ill, as to be universally condemned, though it has since been agreed that he had the better side of the question. In 1671 he attacked Newton's New Theory of Light and Colours; where, though he was obliged to submit in respect to the argument, it is said he came off with more credit. The Royal Society having commenced their meetings at Gresham-college, November 1674, the committee in December allowed him 40*l.* to erect a turret over part of his lodgings, for trying his instruments, and making astronomical observations: and the year following he published A Description of Telescopes, and some other instruments made by R. H. with a Postscript, complaining of some injustice done him by their secretary Mr. Oldenburg, who published the Philosophical Transactions, in regard to his invention of pendulum watches. This charge engaged him in a dispute with that gentleman, which ended in a declaration of the Royal Society in their secretary's favour. Mr. Oldenburg dying in 1677, Mr. Hooke was appointed to supply his place, and began to take minutes at the meeting in October, but did not

publish the Transactions. Soon after this, he became more reserved than formerly; and, though he read his Cutlerian Lectures, often made experiments, and showed new inventions before the Royal Society, yet he seldom left any account of them to be entered in their registers; designing, as he said, to publish them himself, which however he never performed. In 1686, when Newton's work the Principia was published, Hooke laid claim to his discovery concerning the force and action of gravity, which was warmly resented by that great philosopher. Hooke, though a great inventor and discoverer himself, was yet so envious and ambitious, that he would fain have been thought the only man who could invent and discover anything. This made him often lay claim to the inventions and discoveries of other persons; on which occasions, however, as well as in the present case, the thing was generally carried against him.

In the beginning of the year 1687, his brother's daughter, Mrs. Grace Hooke, who had lived with him several years, died: and he was so affected with grief at her death, that he never recovered it, but was observed from that time to become less active, more melancholy, and more cynical than ever. At the same time, a chancery suit, in which he was concerned with Sir John Cutler, on account of his salary for reading the Cutlerian Lectures, made him uneasy, and increased his disorder. In 1691, he was employed in forming the plan of the hospital near Hoxton, founded by Robert Ask, alderman of London, who appointed Archbishop Tillotson one of his executors; and in December the same year, Hooke was created M.D. by a warrant from that prelate. In July 1696, the chancery suit with Sir John Cutler was determined in his favour, to his inexpressible satisfaction. His joy on that occasion was found in his diary thus expressed; DOMSILCISA; that is, *Deo, Optimo, Maximo, sit honor, laus, gloria, in sacula sacerdorum, Amen.* "I was born on this day of July 1635, and God hath given me a new birth: may I never forget his mercies to me! while he gives me breath may I praise him!" In the same year 1696, an order was granted to him for repeating most of his experiments at the expense of the Royal Society, on a promise of his finishing the accounts, observations, and deductions from them, and of perfecting the description of all the instruments contrived by him: but his increasing illness, and general decay, rendered him unable to perform it. He continued some years in this wasting condition; and thus languishing till he was quite emaciated, he died March 3, 1702, in his 67th year, at his lodgings in Gresham-college, and was buried in St. Helen's church, Bishopsgate-street; his corps being attended by all the members of the Royal Society then in London.

With regard to Mr. Hooke's character, it is not in all respects one of the most amiable. In his person he made rather a despicable figure, being but of a short stature, very crooked, pale, lean, and of a meagre aspect, with dark-brown hair, very long, and hanging over his face, lank and uncut. Suitable to his person, his temper was peevish, melancholy, and mistrustful: and, though possessed of great philosophical knowledge, and strong invention, he had so much ambition, that he would be thought the only man who could invent or discover; and hence he often laid claim to the inventions and discoveries of others, while he boasted of many of his own which he never communicated. In the religious part of his character, he was so exemplary, that he always expressed a great veneration

for the Deity ; and seldom received any remarkable benefit in life, or made any considerable discovery in nature, or invented any useful contrivance, or discovered any difficult problem, without noting some professions of acknowledgment to God ; as many places in his diary plainly show. His chief publications are,

1. *Lectiones Cutlerianæ*, or the Cutlerian Lectures.—2. *Micrographia*, or Descriptions of Minute Bodies made by Magnifying Glasses.—3. A Description of *Heliocopes*.—4. A Description of some Mechanical Improvements of Lamps and Water-poises.—5. Philosophical Collections.—6. Posthumous Works, collected from his papers by Richard Waller, secretary to the Royal Society. Besides a number of papers in the *Philos. Trans.* volumes 1, 2, 3, 5, 6, 9, 16, 17, 22.

HORARY, something relating to Hours. As,

HORARY Circles, hour lines, marking the hours, or drawn at the distance of hours from one another.

HORARY Motion, is the motion or space moved in an hour. Thus, the horary motion of the earth on her axis, is 15° ; for, completing her revolution of 360° , in 24 hours, therefore the motion in one hour will be the 24th part of 360° , which is 15 degrees.

HORIZON, a great circle of the sphere, dividing the world into two parts, or hemispheres; the one upper, and visible; the other lower, and hid. The horizon is either rational or sensible.

HORizon, *Rational*, *True*, or *Astronomical*, called also simply and absolutely the horizon, is a great circle having its plane passing through the centre of the earth, and its poles are the zenith and nadir. Hence all the points of the horizon, quite around, are at a quadrant distance from the zenith and nadir. Also the meridian and vertical circles cut the horizon at right angles, and into two equal parts.

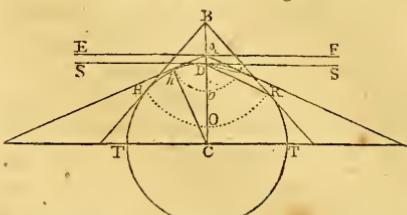

HORIZON, Apparent, Sensible, or Visible, is a lesser circle of the sphere, parallel to the rational horizon, dividing the visible part of the sphere from the invisible, and whose plane touches the spherical surface of the earth. The sensible horizon is divided into eastern and western; the eastern or rising being that in which the heavenly bodies rise; and the western, or occidental, being that in which they set.

HORIZON, in Geography, is a circle dividing the visible part of the earth and heavens from that which is invisible. This is peculiarly called sensible or apparent horizon, to distinguish it from the rational or true, which passes through the centre of the earth; as already observed. These two horizons, though distant from one another by the semidi-
ameter of the earth, will appear to coincide when continued to the sphere of the fixed stars; because the earth compared with this sphere is but a point.

By sensible horizon is also often meant a circle which determines the segment of the surface of the earth, over which the eye can reach; called also the physical horizon. And in this sense we say, a spacious horizon, a narrow or scanty horizon, &c; depending chiefly on the height the eye is elevated above the earth.

For, it is evident that the higher the eye is placed, the farther is the visible horizon extended. Thus, if the eye be at A , at the height AD above the earth; draw the two tangents AB, AR ; and let one of these lines AB , be moved round the point A , and in its revolution always touch the surface of the earth; then the other point B will describe the visible horizon h or r , &c. But if the eye be placed

higher as at B, the tangents BH and BR will reach farther, and the visible horizon HOP will be larger.

The visible horizon is most accurately observed at sea, and is sometimes called the horizon of the sea. In observing this horizon, the visual rays Ah and Ar will, on account of the curve surface of the sea, always point a little below the true sensible horizon ss or EE , and consequently below the rational horizon TT , which is parallel to it.

To find the depression of the horizon of the sea below the true horizon, which varies with the height of the eye, and in a small degree with the variation of the refractive power of the atmosphere, see DEPRESSION.

As to the right-lined distance, or tangent Ah , it may be found thus; as radius : sin. $\angle C :: CA : Ah$, or thus; as radius : tan. $\angle C :: ch : Ah$; either of which will be nearly the same as the arc or curved distance ph . Or, without finding the angle C , thus; the square of Ah is equal to the difference of the squares of CA and ch , i.e. $Ah^2 = CA^2 - ch^2 = (CA + ch) \times (CA - ch) = (CA + ch) \times Ap$, and hence $Ah = \sqrt{(CA + ch \times Ap)}$, which is also equal to the curve ph nearly.

The distance on a perfect globe, if the visual rays came to the eye in a straight line, would be as above stated: but by means of the refraction of the atmosphere, distant objects on the horizon appear higher than they really are, or appear less depressed below the true horizon ss , and may be seen at a greater distance, especially on the sea. M. Legendre, in his *Mémoire on Measurements of the Earth*, in the Mem. Acad. Sci. for the year 1787, says that, from several experiments, he is induced to allow for refraction a 14th part of the distance of the place observed, expressed in degrees and minutes of a great circle. Thus, if the distance be 14000 toises, the refraction will be 1000 toises, equal to the 57th part of a degree, or $1' 3''$. But the English, and other later measurements, make the allowance a 12th part; which therefore on the same distance will be 1167 toises, or the 49th part of a degree, equal to $1' 13''$.

HORIZON of the *Globe*, the broad wooden circle.

HORIZONTAL, something that relates to the horizon, or that is taken in the horizon, or on a level with or parallel to it. Thus, we say, a horizontal plane, horizontal line, horizontal distance, &c.

HORIZONTAL Dial, is one drawn on a plane parallel to the horizon; having its gnomon or style elevated according to the altitude of the pole of the place it is designed for.

HORIZONTAL Distance, is that estimated in the direction of the horizon.

HORIZONTAL Line, in Perspective, is a right line drawn through the principal point, parallel to the horizon; or it is the intersection of the horizontal and perspective planes.

HORIZONTAL Line, or base of a hill, in Surveying, a

line drawn on the horizontal plane of the hill, or that on which it stands.

HORIZONTAL Moon. See *Apparent MAGNITUDE.*

HORIZONTAL Parallax. See *PARALLAX.*

HORIZONTAL Plane, is that which is parallel to the horizon of the place, or not inclined to it.

HORIZONTAL Plane, in Perspective. See *PLANE.*

HORIZONTAL Projection. See *PROJECTION*, and *MAP.*

HORIZONTAL Range, of a piece of ordnance, is the distance it throws its shot on a horizontal plane, whatever be the angle of elevation or direction of the piece. When the piece is pointed parallel to the horizon, the range is then called the point-blank or point-blanc range.—The greatest horizontal range, in the parabolit theory, or in a vacuum, is that made with the piece elevated to 45 degrees, and is equal to double the height from which a heavy body must freely fall, to acquire the velocity with which the shot is discharged. Thus, a shot being discharged with the velocity of v feet per second; because gravity generates the velocity $2g$ or $\frac{32}{4}$ feet in the first second of time, by falling $16\frac{1}{2}$ or g feet, and because the spaces descended are as the squares of the velocities, therefore as $4g^2 : v^2 :: g : \frac{v^2}{4g}$ the space a body must descend to acquire the velocity v of the shot, or the space due to the velocity v ; consequently the double of this, or $\frac{v^2}{2g} = \frac{v^2}{32\frac{1}{4}}$

is the greatest horizontal range with the velocity v , or at an elevation of 45 degrees; which is nearly half the square of a quarter of the velocity.

In other elevations, the horizontal range is as the sine of double the angle of elevation; so that, any other elevation being e , it will be, as radius 1 : sin. $2e :: \frac{v^2}{32\frac{1}{4}} : \frac{v^2}{32\frac{1}{4}} \times \sin. 2e$, the range at the elevation e , with the velocity v .

But in a resisting medium, like the atmosphere, the actual ranges fall short of those expressed by the above theorems, in so much that with the great velocities, the actual or real ranges may be less than the 10th or 20th part of the potential ranges; so that some balls, which actually range but a mile or two, would in vacuo range 20 or 30 miles. And hence also it happens that the elevation of the piece, to shoot farthest in the resisting medium, is always below 45°, and gradually the more below it, as the velocity is greater; so that the greater velocities with which balls are discharged from cannon with gun-powder, require an elevation of the gun equal to but about 30°, or little more. And the less the size of the balls is too, the less must this angle of elevation be, to throw them the farthest with a given velocity. See *PROJECTILE*, and *GUNNERY.*

HORIZONTAL Refraction. See *REFRACTION.*

HORIZONTAL Speculum, one to find a horizon at sea, &c, when the atmosphere is hazy near the horizon, by which the sight of it is prevented. A speculum of this kind was invented by a Mr. Serson, on the principle of a top spinning, which always keeps its upright position, notwithstanding the motion of the substance it spins upon. This curious instrument, as it has since been improved by Mr. Smeaton, consists of a well polished metal speculum, of about 3 inches and a half in diameter, inclosed within a circular rim of brass; so fitted that the centre of gravity of the whole shall fall near the point on which it spins. This is the end of a steel axis running through the centre of the speculum, above which it finishes in a square, for

the conveniency of fitting a roller on it, which sets it in motion by means of a piece of tape wound about the roller. Various other contrivances to form artificial horizons have been invented by different persons, as glass planes floating on mercury, &c. See *HADLEY'S QUADRANT*, and several inventions of this sort by Elton, Halley, Leigh, &c, in the *Philos. Trans.* vol. 37, pa. 273, vol. 38, pa. 167, vol. 40, pa. 413, 417, &c.

HORN-Work, in Fortification, a kind of out-work, advancing towards the field, to cover and defend a curtain, bastion, or other place, suspected to be weaker than the rest; as also to possess a height; carrying in the fore-part, or head, two demi-bastions, resembling horns: these horns, epaulments, or shoulderings, being joined by a curtain, shut up on the side by two wings, parallel to each other, are terminated at the gorge of the work, and so present themselves to the enemy.

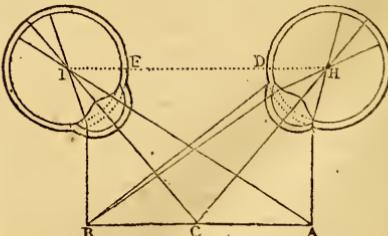

HOROGRAPHY, the art of making or constructing dials; called also *Dialling*, *Horolography*, *Gnomonica*, *Sciatherica*, *Photoscatherica*, &c.

HOROLOGIUM, a common name, among ancient writers, for any instrument or machine for measuring the hours. See *CLOCK*, *WATCH*, *SUN-DIAL*, *CHRONOMETER*, *CLEPSYDRA*, &c.

HOROLOGY, that branch of mechanical science which enables us to measure the portions of time. We judge of the lapse of time by the succession of sensible events; and the most convenient and accurate measures of its quantity are derived from motions; either uniform, or else repeated at equal intervals. Of the former kind, the rotation of the earth on its axis is the most exact, and the situation of its surface with regard to the fixed stars, or less simply, with regard to the sun, constitutes the means for determining the parts of time as they follow each other. Of the latter kind, the rotation of machinery, consisting of wheel-work moved by a weight or spring, and regulated by a pendulum or balance, affords instruments of which the utility is well known. The term horology is at present more particularly confined to the principles on which the art of making clocks and watches is established. A considerable portion of this extended subject of research is given under the article *CLOCK*. See also *Scapement*, *Watch*, &c.

HOROMETRY, the art of measuring or dividing time by hours, and keeping the account of time.

HOROPTER, in Optics, is a right line drawn through the point where the two optic axes meet, parallel to that which joins the centres of the two eyes, or the two pupils. As the line *AB* drawn through *c* the point of concourse of

the optic axes of the eyes, and parallel to *CD* joining the centres of the eyes.—This line is called the horopter, because it is found to be the limit of distinct vision. It has

several properties in Optics, which are described at large in *Aguilonius*, Opt. lib. 2, diss. 10.

HOROSCOPE was mathematical instrument, in manner of a planisphere; but now disused. It was invented by J. Paduanus, who wrote a special treatise upon it.

HORROR of *a Vacuum*, an imaginary principle among the more ancient philosophers, to which they ascribed the ascent of water in pumps, and other similar phenomena, which are now known to be occasioned by the weight of the air.

HORROX (JEREMIAH), an eminent English astronomer, was born at Toxteth in Lancashire, about the year 1619. From a grammar school in the country, he was sent to Cambridge, where he spent some time in academic studies. About 1633 he began to apply himself to the study of astronomy: but living at that time with his father at Toxteth, in very moderate circumstances, and being destitute of books and other assistances for such studies, he could not make any considerable progress in it. About the year 1636, he formed an acquaintance with Mr. William Crabtree, of Broughton near Manchester, who was engaged in the same studies, with whom a mutual correspondence was carried on till his death; sometimes communicating their improvements to Mr. Samuel Foster, professor of geometry at Gresham College in London. Having now obtained a companion in his studies, Mr. Horrox assumed new vigour, procured other instruments and books, and was pursuing his studies and observations with great assiduity, when he was suddenly cut off by death, the 3d of January 1640, in the 22d year of his age.

What we have of his writings is sufficient to show how great a loss the world had by his death. He had just finished his *Venus in Sole visa*, 1639, a little before, as appears by some of the letters to his friend Mr. Crabtree, by which also it appears that he made his observations on that phenomenon at Hool near Liverpool. This tract, of Venus seen in the Sun, was published at Dantzick in 1668, by Hevelius, together with his own *Mercurius in Sole visus* May 3, 1661. His other posthumous works, or rather his imperfect papers, were published by Dr. Wallis, in 1673, 4to, with some account of his life; in which we find he first asserts and promotes the Keplerian astronomy, against the hypothesis of Lansberg; which he proves to be inconsistent with itself, and neither agreeing with observations nor theory. He likewise reasons very justly concerning the celestial bodies and their motions, vindicates Tycho Brahe from some objections made to his hypothesis, and gives a new theory of the moon: to which are added the Lunar Numbers of Mr. Flamsteed. There are also extracts from several letters between him and Mr. Crabtree, upon various astronomical subjects; with a catalogue of astronomical observations.

There are two things particularly which will perpetuate the memory of this very extraordinary young man. The one is, that he was the first that ever predicted or saw the planet Venus in the sun; for we do not find that any persons, besides himself and Mr. Crabtree, ever beheld such a phenomenon. Though he was not apprised of the great use that was to be made of this phenomenon, in discovering the parallax and distance of the sun and planets, yet he made from it many useful observations, corrections, and improvements in the theory of the motions of Venus. — Secondly, his New Theory of Lunar Motions, which Newton himself made the ground-work of all his astronomy, relative to the moon, who always spoke of our author as a genius of the first rank.

HORSE-SHOE, in Fortification, is a work sometimes of a round, sometimes of an oval figure, inclosed with a parapet, raised in the ditch of a marshy place, or in low grounds; sometimes also to cover a gate; or to serve as a lodgment for soldiers, to prevent surprises, or to relieve an over-tedious defence.

HORSLEY, (SAMUEL, LL.D. and F. R. S.), a very able mathematician and a learned primate, was born in October 1732, and died October 4, 1806; consequently about 74 years of age.—He received the elements of his education at Westminster-school, whence he was removed to the university of Cambridge. There he chiefly applied to the study of mathematics; and not content with carefully consulting the writings of the acutest of the moderns, he recurred to the profoundest of the ancients in that line, and made himself master of their most intricate reasonings. Having taken his degree as master of arts, he accepted an invitation to accompany the late Earl of Aylesford, as private tutor, to Oxford. Here, in 1769, Dr. Horsley printed his edition of the Geometrical Inclinations of Apollonius, and here he first conceived the design of publishing a complete edition of the works of Sir Isaac Newton, for which he began to prepare the materials. And from that time, it has been more the fashion to cultivate the mathematical sciences at that university. On leaving this place, Dr. Horsley came to London, where he was elected F. R. S. and enriched the Philos. Trans. with many valuable essays, from vol. 57, to vol. 66. He was also chosen one of the secretaries in 1773, on the resignation of Dr. Morton; an office he continued to serve, with the greatest credit to himself and benefit to science, till he thought it proper to resign along with the late president Sir John Pringle, in 1778. Soon after settling in the metropolis, Dr. Horsley was noticed by Bishop Louth, and was appointed his lordship's domestic chaplain, as well as was presented by that prelate successively to several different livings. In 1776, Dr. Horsley published proposals for a complete edition of the works of the immortal Newton, with notes, which appeared in 1779, in 5 vols. 4to, with an elegant Latin dedication to the king. In 1778 he preached and published a sermon against the principles of materialism, agitated between the doctors Price and Priestley &c: and on the publication, in 1783, of Dr. Priestley's History of the Corruptions of Christianity, Dr. Horsley again attacked the positions and principles of that writer and his adherents, with great applause and success, and there ensued an exchange of several pamphlets, &c, on both sides; which chiefly laid the foundation of Dr. Horsley's elevation to the episcopal dignity in 1788, assisted probably, by the very celebrated speeches he made in the course of the violent debates, that took place in the Royal Society 2 or 3 years before, on the occasion of the removal of Dr. Hutton from the office of foreign secretary, when Dr. Horsley, and several other members, forsook, as expressed in his own forcible language, "that temple where Philosophy once reigned, and where Newton presided as her officiating minister." In 1794, Dr. Horsley was translated from St. David's to the see of Rochester, with the deanery of Westminster; and in 1802, to the lucrative see of St. Asaph. In 1801 he published the first, and in 1803 the last, of 3 octavo volumes of practical mathematics, for the use of students; consisting of Euclid's Elements and Data, with notes; the properties and projection of the sphere, and spherical trigonometry; Archimedes on the mensuration of the circle; a tract on the nature and use of logarithms, &c. Besides

these, numerous and important were the writings and labours of Dr. Horsley in theology, politics, &c, too numerous to be here entered into in detail.

Doctor Horsley went down to Brightelmstone in the latter end of September 1806, where he had not been two weeks, before he was seized with a complaint in the bowels, then frequent in the place, which soon turned to a mortification; and terminated his valuable existence on the 4th day of his illness. Though Doctor Horsley had reached the 74th year of his age, the powers both of his body and mind were so vigorous, as to promise still a considerable length of years; indeed he was always of a very remarkably active, and energetic cast of mind, and firm compact constitution of body. Perhaps no man of the age, possessed more of what is termed recondite learning; or was more profoundly versed in classical chronology. As a senator, he ranked in the first class; there were few important discussions in the house of lords, in which he did not participate; especially when the topics related to the hierarchical establishments of the country, or to the French revolution, or to the African slave trade, of which he was a systematic opposer. As an orator, his voice was deep, full-toned, and commanding; his enunciation was distinct and clear; and his delivery in other respects, highly advantageous; abating only for a remarkable mixture of certain guttural sounds, such as are almost peculiar to the inhabitants of the county of Northumberland; occasioned, he used to say, by the circumstance of a nurse from that part of England being long employed in his father's family.

HOSPITAL, or HOPITAL (WILLIAM-FRANCIS ANTHONY, marquis of), a celebrated French mathematician, was born of an ancient family in 1661. He was a mathematician almost from his infancy; for being one day at the duke of Rohan's, where some able mathematicians were speaking of a problem of Pascal's, which appeared to them very difficult, he ventured to say, that he believed he could resolve it. They were surprised at such presumption in a boy of 15: however, in a few days he sent them the solution. M. l'Hospital entered early into the army, and was a captain of horse; but being very short-sighted, and on that account exposed to perpetual inconveniences and errors, he at length quitted the army, and applied himself entirely to his favourite amusement.—He contracted friendship with Malbranche, and took his opinion upon all occasions.—In 1699 he was received an honorary member of the Academy of Sciences at Paris.—He was the first person in France who wrote upon Newton's analysis, and on this account was regarded almost as a prodigy. His work was entitled *l'Analyse des Infinites Petits*, 1696. He engaged afterwards in another mathematical work, in which he included *Les Sections Coniques*, *les Lieux Géométriques*, *la Construction des Equations*, et une Théorie des Courbes Mécaniques: but, a little before he had finished it he was seized with a fever, which carried him off, the 2d of February 1704, at 43 years of age. The work was published after his death, viz, in 1707. Six of his pieces are inserted in different volumes of the Memoirs of the Academy.

HOUR, in Chronology, an aliquot part of a natural day, usually the 24th, but sometimes a 12th part. With us, it is the 24th part of the earth's diurnal rotation, or the time from noon to noon, and therefore it answers to 15 degrees of the whole circle of longitude, or of 360° . The hour is divided by 60ths, viz, first into 60 minutes, then each minute into 60 seconds, &c. The division of the day

into hours is very ancient; as is shown by Kircher, *Oedip. Egypt.* tom. 2, par. 2, class 7, cap. 8. The most ancient hour is that of the 12th part of the day. Herodotus, lib. 2, observes, that the Greeks learnt from the Egyptians, among other things, the method of dividing the day into 12 parts. And the astronomers of Cathaya, &c, still retain this division.

The division of the day into 24 hours, was not known to the Romans before the Punic war. Till that time they only regulated their days by the rising and setting of the sun. They divided the 12 hours of their day in four; viz, Prime, which commenced at 6 o'clock, Third at 9, Sixth at 12, and None at 3. They also divided the night into four watches, each containing 3 hours. Various kinds of hours are used by chronologers, astronomers, dialists, &c. Sometimes too,

Hours are divided into equal and unequal.

Equal Hours, are the 24th parts of a day and night precisely; that is, the time in which the 15 degrees of the equator pass the meridian.* These are also called equinoctial hours, because measured on the equinoctial; and astronomical, because used by astronomers.

Astronomical Hours, are equal hours, reckoned from noon to noon, in a continued series of 24.

Babylonish Hours, are equal hours, reckoned from sunrise in a continued series of 24.

European Hours, used in civil computation, are equal hours, reckoned from midnight; 12 from thence till noon, and 12 more from noon till midnight.

Ancient or Jewish Hours, are twelfth parts of the artificial day, or of the night. Hence, as it is only at the time of the equinoxes, that the artificial day is equal to the night, it is then only that the hours of the day are equal to those of the night, or to the 24th part of the natural day. From the vernal to the autumnal equinox, the hours of the day exceed those of the night; but during the interval between the autumnal and vernal equinoxes, the hours of the night are longer than those of the day. It is therefore manifest, that when it is said the third hour was about nine in the morning, and the ninth about three in the afternoon, this is not to be understood as rigorously exact. The third hour was the middle time between sunrise and noon; which, if the sun rose at five, was half an hour after eight; if at seven was half an hour after nine, &c.

The following table exhibits the time of the sun-rising and setting, and the length of the Jewish hour, both of day and night; as calculated for about the middle of every Jewish month, and for the latitude of Jerusalem.

Names of the Months.	Sun rises.	Sun sets.	Length of the Hour		
			of day.	of night.	of day.
Nisan, or Abib	-	5 40	6 14	1 0	5 58
Ijar, or Zif	-	5 20	6 40	1 7	0 53
Sivan	-	5 0	7 0	1 10	0 50
Thamuez	-	4 56	7 4	1 11	0 49
Ab	-	5 10	6 50	1 8	0 52
Elul	-	5 36	6 24	1 4	0 56
Tisri, or Ethanim	6 6	5 54	0 59	1	1
Nearchewan, or Bul	6 34	5 26	0 54	1	6
Chisleu	-	6 55	5 5	0 51	1 9
Tebeth	-	7 0	5 0	0 50	1 10
Shebat	-	6 42	5 18	0 53	1 7
Adar	-	6 16	5 44	0 57	1 3

Italian Hours, are equal hours, reckoned from sunset, in a continued series of 24.

Unequal or Temporary Hours, are 12th parts of the artificial day and night. The obliquity of the sphere renders these more or less unequal at different times; so that they only agree with the equal hours at the times of the equinoxes.

Hour-Circles, or *Horary-Circles*, are great circles, meeting in the poles of the globe or world, and crossing the equinoctial or equator at right angles; the same as meridians. They are supposed to be drawn through every 15th degree of the equinoctial and equator, each answering to an hour, and dividing them into 24 equal parts; and on both globes they are supplied by the meridian hour-circle and index.

Hour-Glass, a popular kind of chronometer or clepsydra, serving to measure time by the descent or running of sand, water, &c, out of one glass vessel into another. The best, it is said, are such as, instead of sand, have egg-shells, well dried in the oven, then beaten fine and sifted.

Hour-Lines, on a dial, are lines which arise from the intersections of the plane of the dial, with the several planes of the hour-circles of the sphere; and therefore must be all right lines on a plane dial.

Hour-Scale, a divided line on the edge of Collins's quadrant, being only two lines of tangents of 45 degrees each, set together in the middle. Its use, together with the lines of latitude, is to draw the hour-lines of dials that have centres, by means of an equilateral triangle, drawn on the dial-planes.

HOWITZ, or *HOWITZER*, in artillery, a kind of mortar, or something between a cannon and mortar, partaking of the nature of both, being either a very short gun or a long mortar. It is of German invention, and is mounted on a carriage like a travelling gun-carriage, with its trunions placed nearly in the middle. The howitz is one of the most useful kinds of ordnance, as it can be employed occasionally either as a cannon or mortar, discharging either shells or grape-shot, as well as balls, and so doing great execution. They are also very easily travelled about from place to place.

HUDE (JOHN), a burgomaster of Amsterdam, and a respectable mathematician, who died at a great age in 1704. Having been as great in politics as in mathematics, he served his country in distinguished situations, and contributed, by his discoveries, to the advancement of the sciences. He applied himself particularly to the analysis of equations. One of his two letters, inserted in Schooten's Commentary on the Geometry of Descartes, contains a very ingenious method for discovering whether an equation of any dimension has equal roots, and for determining those roots. In the same letters we find Hudde's methods of drawing tangents to curves, and of investigating the maxima and minima in mathematics.

HUES (ROBERT), was born at Little Hereford, in Herefordsire, about 1552, and studied at Oxford. He became eminent for his knowledge in geography, navigation, and mathematics; which acquired him particularly the favour of that noble Macenas, Henry earl of Northumberland, being one of the earls so called three magi; from whom he enjoyed a liberal pension, for the encouragement and promotion of his studies. He died in 1632, at 79 years of age, and was buried at Christ's Church, Oxon.—His publications were chiefly two; viz. 1. *Breviarium totius Orbis*; printed several times at London, in

VOL. I.

Latin and English, in 8vo and 12mo.—2. *De Globis celest. et terrest. Tract. 2*; several times printed in Latin and English, in 8vo. The first edition was printed at London 1593, in 8vo. It was afterwards improved by annotations, and illustrated with figures, by Job. Isaac Pontanus, professor of philosophy at Harderwicke, in Gelderland, printed at Amsterdam, 1617, 1624, &c, at London, 1639, and at Oxon, 1663, in 8vo and 12mo. See Wood, vol. 1, pa. 489.

Hues was man of letters, and had acquired a practical knowledge of maritime affairs, by voyages at sea. Among other curious particulars, he gives a good account of the attempts that had been made at various times to measure the earth: in the epistle to Sir Walter Raleigh, he enumerates the many discoveries made by our mariners in different parts of the world. His book was received with great applause, and has been indeed a pattern for such as afterwards treated on the same subject. Among other problems, he solves by the globe, the problem of determining the latitude, from two observations of the sun's altitude, when the time between the two observations is given; and in the last part of his book, he performs the usual questions in navigation, premising a very sensible discourse on the rhumb-lines, opposing the opinion of Gemma Frisius, who had asserted, that they meet in the poles. At the conclusion, he highly praises a treatise of Mr. Thomas Hariot, hoping it would soon be published, in which that author had treated this subject on geometrical principles, with great sagacity and judgment. But unfortunately that manuscript has not been found among the papers of that author, lately discovered by Dr. Zach.

It was in this book that Hues proposed a curious nautical problem, which has made a considerable sensation in the mathematical world. It was in these words, as translated into English: "The difference of longitude and the distance being given, how to find the rumbe, and the difference of latitude." After which he adds these words: "There is not anything in all this art more difficult and hard to be found, than the rumbe out of the distance and difference of longitude given. Neither can it be done upon the globe without long and tedious practice, and many repetitions and mensurations."

The next person who appears to have mentioned this problem, was Willebrord Snell, professor of mathematics at Leyden, in his *Tiphys Batavus*, printed in 1624, being the 34th or last proposition of the first book of that work. Snell solved this problem in an indirect way; and it seems probable that his solution was the first that ever was given of it.

The problem was afterwards proposed to the learned world, by the celebrated Dr. Halley, in the year 1696, in the *Philos. Trans.* vol. 19, No. 219; whence it was repeated in the 2d vol. of the *Miscellanea Curiosa* in 1708, as he had probably not seen it in either of the foregoing authors. Dr. Halley proposes it in the following words: "A ship sails from a given latitude, and, having run a certain number of leagues, has altered her longitude by a given angle; it is required to find the course steered." And he then adds, "The solution hereof would be very acceptable, if not to the public, at least to the author of this tract, being likely to open some further light into the mysteries of geometry."

Since that time, this problem has been solved in an indirect manner, by several writers on navigation, and

others:—As by M. Bouguer, in his *Nouveau Traité de Navigation*; by Mr. Robertson, in the 2d vol. of his *Elements of Navigation*; by Mr. Emerson, in his *Theory of Navigation*; by Mr. Israel Lyons, in the *Nautical Almanack*, 1772; and by M. Bezout, in his *Traité de Navigation*; and lately, Baron Maseres, with the assistance of Mr. Atwood, has given a direct solution of this problem, being the first direct solution that has been given of it. All which solutions may be seen in the 4th vol. of Baron Maseres's work, entitled *Scriptores Logarithmici*.

HUMIDITY, or moisture, the power or quality of wetting or moistening other bodies, and adhering to them. Fluids are moist to some bodies, and not to others. Thus, quicksilver is not moist in respect to our hands or clothes, and other substances, which it will not adhere to; but it may be called humid in reference to gold, tin, or lead, to the surfaces of which it will presently adhere, and render them soft and moist. Even water itself, which wets almost every thing, and is the great standard of moisture and humidity, is not capable of wetting all things; for it stands or runs off in globular-drops from any thing greased or oiled, or the leaves of cabbages, and many other plants; and it will not wet the feathers of ducks, geese, swans, and other water-fowl.

HUNDRED, the number of ten times ten, or the square of 10. The place of hundreds makes the third in order in Arabic or modern numeration, being denoted thus, 100. In the Roman notation it is denoted by the letter c, being the initial of its name, Centum.

HUNDRED Weight, or the great hundred, contains 112 pounds weight. It is subdivided into 4 quarters, and each quarter into 28 lbs.

HURTTERS, in Fortification, denote pieces of timber, about 6 inches square, placed at the lower end of the platform, next to the parapet, to prevent the wheels of the gun-carriages from damaging the parapet.

HYUGENS (CHRISTIAN), a very eminent astronomer and mathematician, was born at the Hague in Holland, in 1629, being the son of Constantine Huygens, lord of Zuylichem, who had served three successive princes of Orange in the quality of secretary. He spent his whole life in cultivating the mathematics; and not in the speculative way only, but also in making them subservient to the uses of life. From his infancy he discovered an extraordinary fondness for the mathematics; in a short time made a great progress in them; and perfected himself in those studies under professor Schooten, at Leyden. In 1649 he went to Holstein and Denmark, in the retinue of Henry, count of Nassau; and was extremely desirous of going to Sweden, to visit Descartes, who was then in that country with the queen Christina, but the count's short stay in Denmark would not permit him.—In 1651 he gave the world a specimen of his genius for mathematics, in a treatise entitled, *Theoremata de Quadratura Hyperbolæ, Ellipsis, et Circuli, ex dato Portionum Gravitatis Centro*; in which he clearly showed what might be expected from him afterwards.—In 1655 he travelled into France, and took the degree of LL.D. at Angers.—In 1658 he published his *Horologium Oscillatorium, sive de Motu Pendulorum, &c.*, at the Hague. He had exhibited in a former work, entitled *Brevia Institutio de Usu Horologiorum ad inveniendas Longitudines*, a model of a new-invented pendulum; but as some persons, envious of his reputation, were labouring to deprive him of the honour of the invention, he wrote this book to explain the construction of it;

and to show that it was very different from the pendulum of astronomers invented by Galileo.—In 1659 he published his *Systema Saturninum, &c.*; in which he first of any one explained the ring of Saturn, and discovered also one of the satellites belonging to that planet, which had hitherto escaped the eyes of astronomers: new discoveries, made with glasses of his own forming, which gained him a high rank among the astronomers of his time.

In 1660, he took a second journey into France, and the year after passed over into England, where he communicated his art of polishing glasses for telescopes, and was made Fellow of the Royal Society. About this time the air-pump was invented, which received considerable improvements from him. This year also he discovered the laws of the collision of elastic bodies; as did also about this time Wallis and Wren, with whom he had a dispute about the honour of this discovery. On his return to France, in 1663, the minister Colbert, being informed of his great merit, settled a considerable pension on him, to engage him to fix at Paris; to which Mr. Huygens consented, and staid there from the year 1666 to 1681, where he was admitted a member of the Academy of Sciences. All this time he spent in mathematical pursuits, wrote several books, which were published from time to time, and invented and perfected several useful instruments and machines: particularly he had a dispute, about the year 1668, with Mr. James Gregory, concerning the quadrature of the circle and hyperbola of the latter, then just published, in which Huygens it seems had the better side of the question. But continual application gradually impaired his health; and though he had visited his native country twice, viz, in 1670 and 1675, for the recovery of it, he was now obliged to betake himself to it altogether. Accordingly he left Paris in 1681, and retired to his own country, where he spent the remainder of his life in the same pursuits and employments. He died at the Hague, June 8, 1695, in the 67th year of his age, while his *Cosmoothores*, or treatise concerning a plurality of worlds, was printing; so that this work did not appear till 1698.

Mr. Huygens loved a quiet and studious manner of life, and frequently retired into the country to avoid interruption, but did not contract that moroseness which is so commonly the effect of solitude and retirement. He was one of the purest and most ingenuous mathematicians of his age, and indeed of any other; and made many valuable discoveries. He was the first who discovered Saturn's ring, and a third satellite of that planet, as mentioned above. He invented the means of rendering clocks exact, by applying the pendulum, and of rendering all its vibrations equal, by the cycloid. He brought telescopes to perfection, and made many other useful discoveries.

He was the author of many excellent works. The principal of these are now contained in two collections, of 2 volumes each, printed in 4to, under the care of professor Gravesande. The first was at Leyden, in 1682, under the title of *Opera Varia*; and the second at Amsterdam, in 1728, entitled *Opera Reliqua*.

HYADES, a cluster of 5 stars in the face of the constellation Taurus, or the Bull.

HYALOIDES, the vitreous humour of the eye, contained between the tunica-retina and the uvea.

HYBERNAL Occident. See OCCIDENT.

HYBERNAL Orient. See ORIENT.

HYDATOIDES, the watery humour of the eye, contained between the cornea and the uvea.

HYDRA, a southern constellation, consisting of a number of stars, imagined to represent a water-serpent. The stars in the constellation Hydra, in Ptolemy's catalogue, are 27; in Tycho's, 19; in Hevelius's, 31; and in the Britannic catalogue, 60.

HYDRAULICS, the science of the motion of water and other fluids, with its application in artificial water-works of all kinds.—As to what respects merely the equilibrium of fluids, or their gravitation or action at rest, belongs to hydrostatics. On removing or destroying that equilibrium, motion ensues; and here hydraulics commence. Hydraulics therefore suppose hydrostatics; and many writers, from the near relation between them, like mechanics and statics, join the two together, and treat of them conjointly as one science.—The laws of hydraulics are given under the word Fluid. And the art of raising water, with the several machines employed for that purpose, are described under their several names, Fountain, Hydrocanister Pump, Siphon, Syringe, &c.

The principal writers who have cultivated and improved hydraulics and hydrostatics, are Archimedes, in his *Libris de Insidentibus Humido*; Hero of Alexandria, in his *Liber Spiritualium*; Marinus Ghetaldus, in his *Archimedes promotus*; Mr. Oughtred; Jo. Ceva, in his *Geometria Motus*; Jo. Bap. Balianus, *De Motu Naturali Gravium, Solidorum et Liquidorum*; Mariotte, in his treatise of the Motion of Water and other Fluids; Boyle, in his Hydrostatical Paradoxes; Fran. Tertius de Lanis, in his *Magisterium Naturae et Artis*; Lamy, in his *Traité de l'Équilibre des Liqueurs*; Rohault; Dr. Wallis, in his Mechanics; Dechales; Newton, in his Principia; Guglielmini, in his *Mensura Aquarum Fluentium*; Herman; Wolfius; Graviesande; Musschenbroek; Leopold; Schottus, in his *Mechanica Hydraulic-Pneumatica*; Geo. Andr. Bockler, in his *Architecture Curiosa Germanica*; August. Ramillieis; Lucas Antonius Portius; Sturmy, in his treatise on the Construction of Mills; Switzer's Hydrostatics; Varignon, in the Mem. Acad. Sci.; Jurin; Belidor; Bernoulli; Desaguliers; Clare; Emerson; Ferguson; Ximenes; Bossu; D'Alembert; Busat; &c., &c.,—See also PUMPS, STEAM Engines, &c.

HYDRAÚLICO-PNEUMATICAL, a term applied by some authors to such engines, as raise water by means of the weight or spring of the air.

HYDRAULIC RAM, the name of a machine by Montgolfier, for raising water.

The ingenious idea of raising water by the momentum of water itself, was first suggested by Mr. Whitehurst in the Philosophical Transactions for 1775. The same principle, in an improved form, has lately been revived in France, and has excited considerable attention both on the continent and in this country. Whatever credit therefore is due to the inventor of the Hydraulic Ram, properly belongs to our countryman Mr. Whitehurst, and Montgolfier can lay claim to nothing more than the merit of an improver.

Mr. Whitehurst's machine, which is represented in fig. 1. pl. 16, was actually erected at Oulton in Cheshire, and completely answered the expectation of its inventor. *AM* is the original reservoir, whose surface is on a level with *B*, the bottom of the reservoir *BN*. The main pipe *AZ*, is $\frac{1}{2}$ inches diameter, and nearly two hundred yards long, and the branch pipe *ER* is of such a size that the cork *R* is about 16 feet below the surface *M* of the reservoir. *D* is a valve box, with its valve *a*, and *c* is an air vessel,

into which are inserted the extremities *m*, *n*, of the main pipe, bent downwards to prevent the air from being driven out when the water is forced into it.

Now, since the difference of level between the cock *r* and the top of the reservoir *AM* is 16 feet, on opening the cock *r* the water will rush out with a velocity of nearly 30 feet per second. A column of water therefore 200 yards long, is thus put in motion, and though the aperture of the cock *r* be small, it must have a very considerable momentum. Let the cock *r* be now suddenly stopped, the water must evidently rush through the valve *a* into the air vessel *c*, and condense the included air. This condensation must take place every time the cock is opened and shut, and the included air being highly compressed, will press upon the water in the air vessel, and raise it into the reservoir *BN*.

From this brief description of Whitehurst's machine, the reader will easily perceive its resemblance to Montgolfier's hydraulic ram, a section of which is represented by fig. 2. *R* is the reservoir, *ns* the height of the fall, and *st* the horizontal tube which conducts the water to the engine *ABNTE*. *E* and *D* are two valves, and *rg* a pipe reaching within a very little of the bottom *cb*. Now let water descend from the reservoir, it will rush out at the aperture *mn* till its velocity becomes so great as to force up the valve *E*. The water being thus suddenly checked, and unable to find a passage at *mn*, will move forwards with great violence and force towards *H*, and raise the valve *D*. A portion of water being admitted into the vessel *ABC*, the impulse of the column of fluid is expended, the valves *D* and *E* fall, and the water rushes out at *mn* as before, when its motion is again stopped, and the same operation repeated which has now been described. Every time therefore that the valve *E* closes, a portion of water will force its way into the vessel *ABC*, and condense the air which it contains; for the included air has no communication with the atmosphere after the water is higher than the bottom of the pipe *rg*. This condensed air will consequently exert great force on the surface *op* of the water, and raise it in the tube *rg*, to a height proportioned to the elasticity of the imprisoned air. The external appearance of the engine, copied from one in the possession of Professor Leslie, is exhibited in fig. 3; where *ABC* is the air vessel, *F* the valve box, *c* the extremity of the valve, and *MN* screws for fixing the horizontal tube to the machine. A piece of brass, *A*, with a small aperture, is screwed on the top, when the engine is employed, to form a jet of water.

From this description, it will easily be perceived that the only difference between the engines of Montgolfier and Whitehurst is, that the one requires a person to turn the cock, while the other has the advantage of acting spontaneously. Montgolfier assures us (*Journal des Mines*, vol. 13, No. 73) that the honour of this invention does not belong to England, but that he is the sole inventor, and did not receive a hint from any person whatever. We leave it to the reader to determine to what degree of credit these assertions are entitled.

It would appear, from some experiments of Montgolfier, that the effect of the water-ram is equal to between $\frac{1}{2}$ and $\frac{3}{4}$ of the power expended; which renders it superior to most hydraulic engines. Appendix to Brewster's Ferguson's Lectures, pa. 419.

The principles on which the ram of Montgolfier is constructed, are susceptible of a very extensive application:

thus, it would be easy to raise other water besides that which runs through the ram; as for example, with a fall of water we might by a slight modification of this machine raise water from the bottom of wells, or even of mines.

Other machines analogous to Montgolfier's engine have been invented by Messrs. Sarjeant and Boulton; and the celebrated hydraulic engine in Chemnitz in Hungary is closely allied to the ram in principle. M. Montgolfier suggests the utility of his invention in the draining of mines; and in that case, the hydraulic ram and the Hungarian machine would become very nearly if not altogether identical as to principle.

HYDRODYNAMICS, that branch of mechanical science which relates to the motion of non-elastic fluids, and the forces with which they act upon bodies opposed to them.

There is no part of mechanics the true theory of which we are so little acquainted with as that which respects the motion of fluids. Nor is it strange that the knowledge we do possess of this science should be so dubious and confined, when we consider the many powerful obstacles which continually present themselves in the cultivation of it. The mass, the figure, and the number of particles of a fluid in motion, are particulars with which we are too superficially acquainted to determine the laws of its motion, with any satisfactory degree of accuracy; and even if we were in possession of the data by which those laws might be determined, it is doubtful whether we should be much farther advanced, as it might be extremely difficult to deduce any convenient and practical results from the intricate and complex expressions which might be obtained from the investigation. The greatest mathematicians have been forced to yield to the numerous difficulties of these researches, and to confess that the methods so successfully followed in the mechanics of solid bodies, do not afford any conclusions with respect to fluids, but such as are too general and uncertain for the greater part of particular cases. Whatever we have of this science is almost exclusively due to the labours of modern analysts and geometers; for the only work which has reached us from the ancients is that of Archimedes, in two books, entitled *De Insidentibus humido*, in which the only enquiries respect the sinking and floating of bodies in fluids, their relative gravities, levities, situations and positions, when in *equilibrio*. It is indeed true that some hints, as well as rules, on the motion of fluids, are contained in a treatise attributed to Sextus Julius Frontinus, inspector of public fountains at Rome, under the emperors Nerva, Cœcilius, and Trajan, entitled *De Aquæ ductibus urbis Romæ commentatoris*; but they are not of sufficient importance to deserve much attention by a student in this science. Benedict Castelli was the first who opened the way to a true measure of the flux of waters, in his *Treatise Della Mesura dell' Aquæ Currenti*, which measure he found to depend on the area of the section and the velocity of the water conjointly. The most valuable and important discoveries and theorems in this department of science, are given in Sir Isaac Newton's *Principia*, lib. 2, pr. 36, with the comment: Dan. Bernoulli's *Hydrodynamique*; D'Alembert's *Traité des Fluides*; D. George Juan's *Examen maritimo Theorico Practico*; M. Bosset's *Hydrodynamique*; Buaat's *Principes d' Hydraulique*, and Mr. Eytelwein's *Handbuch der Mechanick und der Hydraulique*. To which may be added an ingenious paper

on the Motion and Resistance of Fluids, by Mr. Vince, in the *Philos. Transact.* for 1795; and those by the late Dr. Matthew Young in the *Irish Trans.*—See **HYDRAULICS**.

HYDROGEN, the basis of what has been generally called inflammable air, and is one of the components of water.

HYDROGEN Gas, an invisible elastic aeriform fluid undecidable by any known cold, and is the only form in which pure hydrogen has ever been exhibited. The specific gravity of this gas varies considerably, according to the manner in which it has been procured. In general, when pure, it is from 6 to 10 or even to 12 times lighter than common air, so that 8 times may be considered as a general average. It is one of the most inflammable substances we are acquainted with; that is to say, it combines with more oxygen than any other body, and occasions more heat by its combustion; it being a well established fact, that hydrogen and oxygen gases, when mixed, produce the most intense heat yet known.

One of the most striking properties of this gas, is that of reducing metallic oxyds to the reguline or nearly reguline state. This is effected by the union of the hydrogen with the oxygen of the metallic oxyd, in consequence of which the hydrogen loses its gaseous form, and with the oxygen produces water. The metallic reduction by hydrogen gas appears to have been first noticed by Dr. Priestley, but the consequent production of water in these cases was suggested by the most important researches of Mr. Cavendish, on the union of hydrogen and oxygen.

From the great levity of hydrogen gas, it has generally been used for filling air-balloons: indeed this appears the only use to which it has at present been applied. The following is the best way of procuring it: Put a quantity of filings of zinc into a vessel which has a glass tube prefixed; then pour upon them sulphuric acid, diluted with 6 or 8 times its quantity of water, and an effervescence will immediately take place; the water will be decomposed, and the oxygen of it will become united to the metal, and the hydrogen gas will be disengaged, and may be conveyed into the body of the balloon. This gas can be procured pure only from water, in which all cases must undergo a decomposition. For the usual properties of this gas, the reader may consult with much interest Aikins's *Chemical Dict.*

HYDROGRAPHICAL Charts or Maps, more usually called sea-charts, are projections of some part of the sea, or coast, for the use of navigation. In these are laid down all the thumbs or points of the compass, the meridians, parallels, &c., with the coasts, capes, islands, rocks, shoals, shallows, &c., in their proper places, and proportions.

For the construction and use of the several kinds of hydrographical maps, see **CHART**, and **SAILING**.

HYDROLOGY, is that part of natural history which examines and explains the nature and properties of water in general.

HYDROMETER, an instrument for measuring the properties and effects of water, as its density, gravity, force, velocity, &c. That with which the specific gravity of water is determined, is often called an acrometer, or water-poise.

The general principle on which the construction and use of the hydrometer depends, has been illustrated under the article **Specific Gravity**; where it is shown that a body specifically lighter than several fluids, will serve to

find out their specific gravities; because it will sink deepest in the fluids whose specific gravity is the least. In fig. 5, pl. 14, if *AB* represent a small even glass tube, hermetically sealed, having a scale of equal divisions marked upon it, with a hollow ball of about an inch in diameter at bottom, and a smaller ball *c* under it, communicating with the first; and into the little ball be put mercury or small shot, before the tube is sealed, so that it may sink in water below the ball, and float or stand upright, the divisions on the stem showing how far it sinks.—If this instrument be dipped in common water, and sink to *D*, it will sink only to some lower point *E* in salt water; but in port wine it will sink to some higher point *F*, and in brandy perhaps to *B*. It is evident that an hydrometer of this kind will only show that one liquid is specifically heavier than another; but the true specific weight of any liquid cannot be determined without a calculation for this particular instrument, the tube of which should be truly cylindrical. Besides, these instruments will not serve for fluids whose densities are much different.

Mr. Clarke constructed a new hydrometer, showing whether any spirits be proof, or above or below proof, and in what degree. This instrument was made of a ball of copper (because ivory imbibes spirituous liquors, and glass is apt to break), to which is soldered a brass wire about a quarter of an inch thick; upon this wire is marked the point to which it exactly sinks in proof spirits; as also two other marks, one above and one below the former, exactly answering to one-tenth above and one-tenth below proof. There are also a number of small weights made to add to it, so as to answer to the other degrees of strength besides those above, and for determining the specific gravities of different fluids. *Philos. Trans. Abr. vol. vii, pa. 392.*

Dr. Desaguliers contrived an hydrometer for determining the specific gravities of different waters, to such a degree of nicety, that it would show when one kind of water was but the 40,000th part heavier than another. It consists of a hollow glass ball of about 3 inches in diameter, charged with shot to a proper degree, and having fixed in it a long and very slender wire, of only the 40th part of an inch in diameter, and divided into tenths of inches, each tenth answering to the 40,000th part, as above. See his *Exper. Philos. vol. 2, pa. 234.*

Mr. Quin and other persons have also constructed hydrometers, with other and various contrivances, and with different degrees of accuracy; but all nearly on the same general principles.

But there is one circumstance which deserves particular attention in the construction and graduation of hydrometers, for determining the precise strength of different brandies, and other spirituous liquors. Mr. Reaumur discovered, in making his spirit-thermometers, that when rectified spirit and water, or phlegm, the other constituent part of brandy, are mixed together, there appears to be a mutual penetration of the two liquors, and not merely juxtaposition of parts; so that a part of the one fluid seems to be received into the interstices of the other; by which it happens, that if a pint of rectified spirit be added to a pint of water, the mixture will be sensibly less than a quart. The variations hence produced in the bulk of the mixed fluid render the hydrometer, when graduated in the usual way by equal divisions, an erroneous measure of its strength; because the specific gravity of the compound is found not to correspond to the mean gravity of the two

ingredients. M. Montigny constructed a scale for this instrument, in the manner before suggested by Dr. Lewis, on actual observation of the sinking or rising of the hydrometer in various mixtures of alcohol and water, made in certain known proportions. *Hist. de l'Acad. Roy. des Sci. 1768;* also Neumann's *Chem.* by Lewis, pa. 450, note r.

M. De Luc has lately published a scheme for the construction of a comparable hydrometer, so that a workman, after having constructed one upon his principles, may make all others similar to each other, and capable of indicating the same degree on the scale, when immersed in the same liquor of the same temperature. This instrument is proposed to be constructed of a ball of flint glass, communicating with a small hollow cylinder, containing such a quantity of quicksilver for a ballast, that the instrument may sink nearly to its top, in the most spirituous liquor, when heated as much as possible; to which is also attached a thin silvered tube, for a scale, &c. The whole description may be seen at large in the *Philos. Trans.* vol. 68, pa. 500. M. Le Roi also published a proposal for constructing comparable hydrometers. See *Hist. de l'Acad. des Scien.* for 1770, Mém. 7.

Mr. Nicholson has made an improvement, by which the hydrometer is adapted to the general purpose of finding the specific gravity, both of solids and fluids (fig. 4, pl. 16). *A* is a hollow ball of copper, *B* a dish affixed to the ball by a short slender stem, *C*; *c* is another dish affixed to the opposite side of the ball by a kind of stirrup. In the instrument actually made, the stem *D* is of hardened steel, $\frac{1}{8}$ of an inch in diameter, and the dish *c* is so heavy as in all cases to keep the stem vertical when the instrument is made to float in any liquid. The parts are so adjusted that the addition of 1000 grains in the upper dish *B* will just sink it in distilled water (at the temperature of 60° of Fahrenheit's thermometer), so far that the surface shall intersect the middle of the stem *D*.

Let it now be required to find the specific gravity of any fluid. Immerse the instrument in it, and by placing weights in the dish *B* cause it to float, so that the middle of its stem *D* shall be cut by the surface of the fluid. Then, as the known weight of the instrument, added to 1000 grains, is to the same known weight added to the weights used in producing the last equilibrium, so is the weight of a quantity of distilled water displaced by the floating instrument, to the weight of an equal bulk of the fluid under examination.

Again, let it be required to find the specific gravity of a solid body, whose weight is less than 1000 grains. Place the instrument in distilled water, and put the body in the dish *B*. Make the adjustment of sinking the instrument to the middle of the stem, by adding weights in the same dish. Subtract those weights from 1000 grains, and the remainder will be the weight of the body. Place now the body in the lower dish *c*, and add more weight in the upper dish *B*, till the adjustment is again obtained. The weight last added will be the loss the solid sustains by immersion, and is the weight of an equal bulk of water. Consequently the specific gravity of the solid is to that of water, as the weight of the body to the loss occasioned by the immersion. Mr. Nicholson observes, "This instrument was found to be sufficiently accurate to give weights true to less than $\frac{1}{20}$ th of a grain." Nicholson's *Philosophy, vol. 2, p. 16.*

HYDROMETRIA, HYDROMETRY, the mensuration

of water and other fluid bodies, their gravity, force, velocity, quantity, &c; including both hydrostatics and hydraulics.

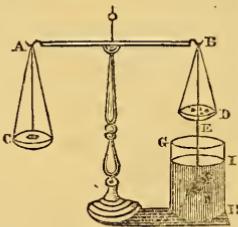

HYDROSCOPE, an instrument anciently used for the measure of time. It was a kind of clepsydra or water-clock, consisting of a cylindrical tube, conical at bottom: the cylinder was graduated with divisions, to which the top of the water becoming successively contiguous, as it trickled out of the vertex of the cone, pointed out the hour.

HYDROSTATICAL Balance, a balance contrived for the exact and easy finding the specific gravities of bodies, both solid and fluid, and thereby of estimating the degree of purity of bodies of all kinds, with the quality and richness of metals, ores, minerals, &c, and the proportions in any mixture, adulteration, or the like. This is effected by weighing the body both in water, or other fluid, and out of it; and for this purpose, one of the scales has usually a hook at the bottom, for suspending the body by some very fine thread. And the use of the instrument is founded on this theorem of Archimedes, that any body weighed in water, loses as much of its weight as is equal to the weight of the same bulk of the water. Thus then is known the proportion of the specific gravities of the solid and fluid, or the proportion of their weights under the same bulk, viz, the proportion of the weight of the body weighed out of water, to the difference between the same and its weight in water. Hence also, by doing the same thing for several different solids, with the same fluid, or different fluids with the same solid, all their specific gravities become known.

This instrument requires but little description. A'B is a nice balance beam, with its scales c and d, turning with the small part of a grain, the one of them, d, having a hook in the bottom, to receive the loop of a horse hair &c, e, by which the body f is suspended. g'h is a jar of water, in which the body is immersed when weighing. The pieces in the scale c denote the weight of the body out of water; then, upon immersing it, put weights in the scale d to restore the balance again, and their quotient will show the specific gravity of the body.

There have been various kinds of the hydrostatical balance, and improvements made on it, by different persons. Thus, Dr. Desaguliers set three screws in the foot of the stand, to move any side higher or lower, till the stem be quite upright, which is known by a plummet hanging over a fixed point in the pedestal. Desag. Exp. Philos. vol. 2, pa. 190. And for sundry other constructions of this instrument, designed for greater accuracy than the common sort, see Martin's Phil. Britan. or Gravesande's Physics Elem. Math. tom. 1, lib. 3, cap. 3, &c.

The specific gravities of small weights may be determined by suspending them in loops of horse hair, or fine silken threads, to the hook at the bottom of the scale. Thus, if a guinea suspended in air weigh 129 grains, and on being immersed in water require $7\frac{1}{2}$ grains to be put in the scale over it, to restore the equilibrium; we thus find that a quantity of water of equal bulk with the guinea,

weighs $7\frac{1}{2}$ grains, or 7·2; therefore dividing the 129 by the 7·2, the quotient 17·88 shows that the guinea is so many times heavier than its bulk of water. Whence, if any piece of gold be tried, by weighing it first in air, then in water, and if, upon dividing the weight in air by the loss in water, the quotient be 17·88, the gold is good; but if the quotient be 18 or more, the gold is more fine; but if it be less than 17·88, the gold is too much alloyed with other metal. If silver be tried in the same manner, and found to be 11 times heavier than water, it is very fine; if it be 10 $\frac{1}{2}$ times heavier, it is standard; but if less, it is mixed with some lighter metal, such as tin.

When the body, whose specific gravity is sought, is lighter than water, so that it will not quite sink; annex to it a piece of another body heavier than water, so that the mass compounded of the two may sink together. Weigh the denser body, and the compound mass, separately, both in water and out of it, thereby finding how much each loses in water; and subtract the less of these two losses from the greater; then say,

As the remainder
is to the weight of the lighter body in air,
so is the specific gravity of water
to the specific gravity of the lighter body.

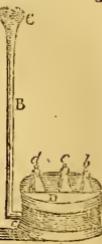

HYDROSTATICAL Bellows, a machine for showing the upward pressure of fluids and the hydrostatical paradox. It consists of two thick boards, A, D, each about 16 or 18 inches diameter, more or less, covered or connected firmly with leather round the edges, to open and shut like a common bellows, but without valves; only a pipe, B, about 3 feet high is fixed into the bellows at c. If water be poured into the pipe at c, it will run into the bellows, gradually separating the boards, by raising the upper one. And if several weights, as three hundred weights, be laid upon the upper board, by pouring the water in at the pipe till it be full, it will sustain them all, though the water in the pipe should not weigh a quarter of a pound; for the pipe or tube may be as small as we please, provided it be long enough, the whole effect depending upon the height, and not at all on the width of the pipe: for the proportion is always this,

As the area of the orifice of the pipe
is to the area of the bellows-board,
so is the weight of water in the pipe
to the weight it will sustain on the board.

Hence if a man stand upon the upper board, and blow into the pipe B, he will raise himself on the board; and the smaller the pipe, the easier he will be able to raise himself; then by putting his finger upon the top of the pipe, he can support himself as long as he pleases, provided the bellows be air-tight.

Mr. Ferguson has described another machine, which may be substituted instead of this common hydrostatical bellows. It is however on the same principle of the hydrostatical paradox; and may be seen in the Supplement to his Lectures, pa. 19.

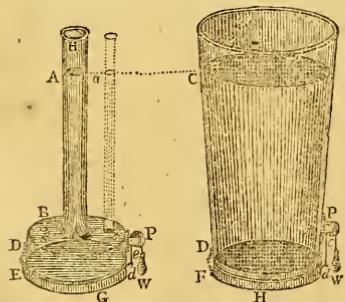

HYDROSTATICAL Paradox, is a principle in hydrostatics, so called because it has a paradoxical appearance at first view: it is this; that any quantity of water, or other fluid, how small soever, may be made to balance and support any quantity, or any weight, how great soever. This is partly illustrated in the last article, on the

hydrostatical bellows, where it appears that any weight whatever may be blown up and supported by the breath from a person's mouth. And the principle may be explained as follows: it is well known that water in a pipe or canal, open at both ends, always rises to the same height at both ends, whether those ends be wide or narrow, equal or unequal. Thus, the small pipe GH being close joined to another open vessel AI , of any size whatever; by pouring water into one of these, it will rise up in the other, and stand at the same height, or horizontal line DF in both of them, and that whether they be upright, or inclined in any position. So that all the water that is in the large vessel from A to I , is supported by that which is in the small vessel from D to I only. And as there is no limit to this latter one, but that it may be made as fine even as a hair, it hence evidently appears that any quantity of water may be thus supported by any other the smallest quantity.

Since then the pressure of fluids is directly as their perpendicular heights, without any regard to their quantities, it appears that whatever the figure or size of the vessels may be, if they are but of equal heights, and the areas of their bottoms equal, the pressures of equal heights of water are equal upon the bottoms of these vessels; even though the one should contain a thousand or ten thousand times as much as the other.

Mr. Ferguson confirms and illustrates this paradox by the following experiment.

Let two vessels be prepared of equal heights, but very unequal contents, such as AB and CD ; each vessel being open at both ends, and their bottoms E and F of equal widths. Let a brass bottom G and H be exactly fitted to each vessel, not to go into it, but for it to stand upon; and let a piece of wet leather be put between each vessel and its brass bottom, to render it as close and tight as possible. Join each bottom to its vessel by a hinge D , so that it may open like the lid of a box; and let each bottom be kept up to its vessel by equal weights w , hung to lines which go over the pulleys P , whose blocks are fixed to

the sides of the vessel at f , and the lines tied to hooks at d , fixed in the brass bottoms opposite to the hinges D . In this adjustment of parts, hold one vessel upright in the hands over a basin on a table, and cause water to be poured slowly into it, till the pressure of the water bears down its bottom at the side d , and raises the weight E ; and then part of the water will run out at d . Mark the height at which the surface n of the water stood in the vessel, when the bottom began to give way at d ; after which, holding up the other vessel in the same manner, cause water to be poured into it; and it will be seen that when the water rises in this vessel just as high as it did in the former, its bottom will also give way at d , and it will also lose part of the water.

The reason of this surprising phenomenon is, that since all parts of a fluid at equal depths below the surface, are equally pressed in all manner of directions, the water immediately below the fixed part n will be pressed as much upward against its lower surface within the vessel, by the action of the column AG , as it would be by a column of the same height, and of any diameter whatever; and therefore, since action and reaction are equal and contrary to each other, the water immediately below the surface n will be pressed as much downward by it, as if it were immediately touched and pressed by a column of the height AG , and of the diameter nf ; and therefore the water in the cavity $BDDf$ will be pressed as much downward upon its bottom G , as the bottom of the other vessel is pressed by all the water above it. Lectures, pa. 105.

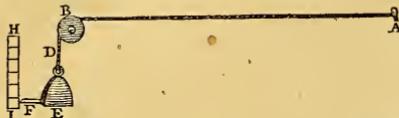

HYDROSTATICS, is that science which treats of the nature, gravity, pressure, and equilibrium of fluids; and of the weighing of solids in them. That part of the science of fluids which considers their motions, being included under the article Hydrodynamics. Hydrostatics and hydrodynamics together constitute a branch of philosophy that is justly considered as one of the most curious, ingenious, and useful of any; affording theorems and phenomena not only of the first use and importance, but also surprisingly amusing and pleasant; as appears in the numberless writings on the subject; the principal points of which may be found under the several particular articles of this work, as **PRESSURE**, **GRAVITY**, &c.

The chief writers who have cultivated and improved this science are, Archimedes, in his *Libris de Insidentibus Humido*; Hero of Alexandria, in his *Liber Spirituum*; Marinus Ghetaulus, in his *Archimedes promotus*; Oughtred; Jo. Ceva, in his *Geometria Motus*; Jo. Bap. Ballianus De Motu Naturali Gravium, Solidorum et Liquorum; Marioke, in his treatise of the Motion of Water and other Fluids; Boyle in his *Hydrostatal Paradoxes*; Boyle in *Tertius de Lanis*, in his *Magisterium Naturae et Artis*; Lamy, in his *Traité de l'Équilibre des Liqueurs*; Rohault; Dr. Wallis, in his Mechanics; Dechales; Newton, in his *Principia*; Gulielmini, in his *Mensura Aquarum Fluentium*; Herman; Wolfius; Gravesande; Muschenbroek; Leopold; Schottus, in his *Mechanica Hydraulic-Pneumatica*; Geo. Andr. Bockler, in his *Architettura Curiosa Germanica*; August Rammelleis; Lucas Antonius Portius; Switzer; Várgnon, in the *Mem. Acad. Sci.*; Jurin; Belidor; Bernoulli; Desaguliers; Clare; Emerson; Ferguson; Ximenes; Bossu; D'Alembert; Buat; Vince; Olinthus Gregory, in his *Mechanics*, &c, &c.

HYDRUS, or *Water Serpent*, one of the new southern constellations, including only ten stars.

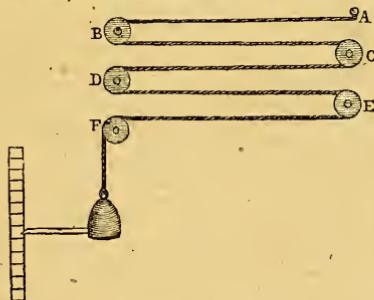

HYEMAL Solstice, the same with Winter Solstice. See **SOLSTICE**.

HYGROMETER, or **HYGROSCOPE**, or **NOTIOMETER**, an instrument for measuring the degrees of moisture in the air. There are various kinds of this instrument; for whatever body either swells by moisture, or shrinks by dryness, is capable of being formed into an hygrometer. Such are woods of most kinds, particularly deal, ash, poplar, &c. Such also is catgut, the beard of a wild oat, and a twisted cord, &c. The best and most usual contrivances for this purpose are as follow.

1. Stretch a common cord, or a fiddle-string, **ABD** along a wall, passing it over a pulley **B**; fixing it at one end **A**, and to the other end hanging a weight **E**, carrying a style or index **F**. Against the same wall fit a plate of metal **H**, graduated, or divided into any number of equal parts; and the hygrometer &c., is complete. For it is matter of constant observation, that moisture sensibly shortens cords and strings; and that, as the moisture evaporates, they return to their former length again. The like may be said of a fiddle-string: and hence it happens that such strings are apt to break in damp weather, if they be not slackened by the screws of the violin. Hence it follows, that the weight **E** will ascend when the air is more moist, and descend again when it becomes drier. By which means the index **F** will be carried up and down, and, by pointing to the several divisions on the scale, will show the degrees of moisture or dryness.

2. Or thus, for a more sensible and accurate hygrometer:

ter: strain a whipcord, or catgut, over several pulleys **B**, **C**, **D**, **E**, **F**; and proceed as before for the rest of the construction. It matters not whether the several parts of the cord be parallel to the horizon, as expressed in the annexed figure, or perpendicular to the same, or in any other position; the advantage of this, over the former method, being merely the having a greater length of cord in the same compass; for the longer the cord, the greater is the contraction and dilatation, and consequently of the degrees of variation of the index over the scale, for any given change of moisture in the air.

3. Or thus: Fasten a twisted cord, or catgut, **AB**, by one end at **A**, sustaining a weight at **B**; carrying an index **C** round a circular scale **DE** described on a horizontal board or table. For a cord or catgut twists itself as it moistens, and untwists again as it dries. Hence, on an increase or decrease of the humidity of the air, the index will show the quantity of twisting or untwisting, and consequently the increase or decrease of moisture or dryness.

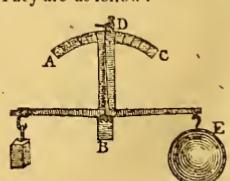

4. Those Dutch toys, called weather houses, where a small image of a man, and another of a woman, are fixed upon the ends of an index, are constructed on this principle. For the index, being sustained by a cord, or twisted catgut, turns backwards and forwards, sending out the man in wet weather, and the woman in dry.

5. Or thus: Fasten one end of a cord, or catgut, **AB**, to a hook at **A**; and to the other end a ball **D** of about one pound weight; upon which draw two concentric circles, and divide them into any number of equal parts, for a scale; then fit a style or index **EC** into a proper support at **E**, so as the extremity **C** may almost touch the divisions of the ball.—Here the cord twisting or untwisting, as in the former case, will indicate the change of moisture, by the successive application of the divisions of the circular scale, as the ball turns round, to the index **C**.

6. Or an hygrometer may be made of the thin boards of ash or fir, by their swelling or contracting. But this, and all the other kinds of this instrument, above described, become in time sensibly less and less accurate; till at last they lose their effect entirely, and suffer no alteration from the weather; in consequence of which, several others of another kind have been invented, much more durable, serving for many years with tolerable accuracy. They are as follow:

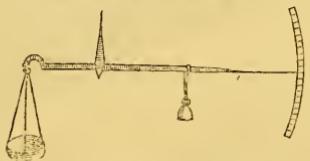

7. Take the manoscope, described under that article, and instead of the exhausted ball **E**, substitute a sponge, or other body, that easily imbibes moisture. To prepare the sponge, it may be proper first to wash it in water very clean; and, when dry again, in water or vinegar in which there has been dissolved sal ammoniac, or salt of tartar; after which let it dry again.—Now, if the air become moist, the sponge will imbibe it and grow heavier, consequently will preponderate, and turn the index towards **C**; on the contrary, when the air becomes drier, the sponge is lighter, and the index turns towards **A**; and thus showing the state of the air.

8. In the last-mentioned hygrometer, Mr. Gould, in the Philos. Trans. instead of a sponge, recommends oil of

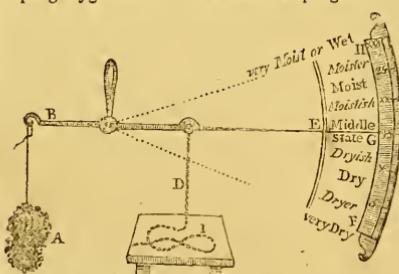

vitriol, which grows sensibly lighter or heavier from the degrees of moisture in the air; so that being saturated in the moistest weather, it afterwards retains or loses its acquired weight, as the air proves more or less dry. The alteration in this liquor is so great, that in the space of 57 days it has been known to change its weight from 3 drachms to 9; and has shifted a tongue or index of a balance 30 degrees. So that in this way a pair of scales may afford a very nice hygrometer. The same author suggests, that oil of sulphur or campanam, or oil of tartar per deliquium, or the liquor of fixed nitre, might be used instead of the oil of vitriol.

9. This balance may be contrived in two ways; by either having the pin in the middle of the beam, with a slender tongue a foot and a half long, pointing to the divisions on an arched plate, as represented in the last figure. Or the scale with the liquor may be hung to the point of the beam near the pin, and the other extremity

made so long, as to describe a large arch on a board placed for the purpose; as in the figure here annexed.

10. Mr. Arderon has proposed some improvement in the sponge hygrometer. He directs the sponge A to be so

cut, as to contain as large a superficies as possible, and to hang by a fine thread of silk upon the beam of a balance B, and exactly balanced on the other side by another thread of silk at D, strung with the smallest lead shot, at equal distances, so adjusted as to cause an index E to point at E, the middle of a graduated arch FGH, when the air is in a middle state between the greatest moisture and the greatest dryness. Under this silk so strung with shot, is placed a small table or shelf I, for that part of the silk or shot to rest upon which is not suspended. When the moisture imbibed by the sponge increases its weight, it will raise the index, with part of the shot, from the table, and vice versa when the air is dry. Phil. Trans. vol. 44, pa. 96.

11. From a series of hygroscopical observations, made with an apparatus of deal wood, described in the Philos. Trans. No. 480, Mr. Coniers concludes, 1st, That the wood contracts most in summer, and swells most in winter, but is most liable to change in the spring and fall. 2d, That this motion happens chiefly in the day time, there

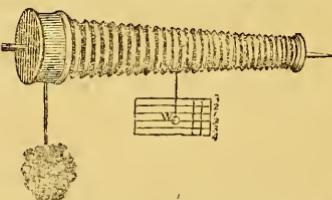

VOL. I.

being scarcely any variation in the night. 3d, That there is a motion even in dry weather, the wood swelling in the morning, and shrinking in the afternoon. 4th, That the wood, by night as well as by day, usually contracts when the wind is in the north, north-east, and east, both in summer and winter. 5th, That by constant observation of the motion and rest of the wood, with the help of a thermometer, the direction of the wind may be told nearly without a weather-cock. He adds also, that even the time of the year may be known by it; for in spring it moves more and quicker than in winter; in summer it is more contracted than in spring; and has less motion in autumn than in summer.

See an account of a method of constructing these and other hygrometers, in various places of the Philos. Trans. as vol. 11, pa. 647 and 715; vol. 15, pa. 1032; vol. 43, pa. 6; vol. 44, pa. 95, 169, and 184; vol. 54, pa. 259; vol. 61, pa. 198; vol. 63, pa. 404, &c. In my Abridg. also the General Index at the end points out the places of reference.

12. Dr. Hooke's hygrometer was made of the beard of a wild oat, set in a small box, with a dial plate and an index. See his Micrographia, pa. 150.

13. The doctors Hales and Desaguliers both contrived another form of sponge hygrometer, on this principle. They made an horizontal axis, having a small part of its

length cylindrical, and the remainder tapering conically with a spiral thread cut in it, after the manner of the fuzees of a watch. The sponge is suspended by a fine silk thread to the cylindrical part of the axis, upon which it winds. This is balanced by a small weight w, suspended also by a thread, which winds upon the spiral fuze. Here, when the sponge grows heavier, in moist weather, it descends and turns the axis, and so draws up the weight, which coming to thicker part of the axis it becomes a balance to the sponge, and its motion is shown by an attached scale. And vice versa when the air becomes drier.—Salt of tartar, or any other salt, or pot-ashes, may be put into the scale of a balance, and used instead of the sponge. Desag. Exper. Philos. vol. 2, pa. 300.

14. Mr. Ferguson made an hygrometer of a thin deal pannel; and to enlarge the scale, and so render its variations more sensible, he employed a wheel and axle, making one cord pass over the axle, which turned a wheel ten times as large, over which passed a line with a weight at the end of it, whose motion was therefore ten times as much as that of the deal pannel. The board should be changed in 3 or 4 years. See Philos. Trans. vol. 54, art. 47.

15. Mr. Smeaton gave also an ingenious and elaborate construction of an hygrometer; which may be seen in the Philos. Trans. vol. 61, art. 24.

16. Mr. Deluc's contrivance for an hygrometer is very ingenious, and on this principle. Finding that even ivory

swells with moisture, and contracts with dryness, he made a small and very thin hollow cylinder of ivory, open only at the upper end, into which is fitted the under or open end of a very fine long glass tube, like that of a thermometer. Into these is introduced some quicksilver, filling the ivory cylinder, and a small part of the length up the glass tube. The consequence is this: when moisture swells the ivory cylinder, its bore or capacity grows larger, and consequently the mercury sinks in the fine glass tube; and vice versa, when the air is drier, the ivory contracts, and forces the mercury higher up the glass tube. It is evident that an instrument thus constructed is in fact also a thermometer, and must necessarily be affected by the vicissitudes of heat and cold, as well as by those of dryness and moisture; or that it must act as a thermometer as well as an hygrometer. The ingenious contrivances in the structure and mounting of this instrument may be seen in the Philos. Trans. vol. 63, art. 38; where it may also be seen how the above imperfection is corrected by some simple and ingenious expedients, employed in the original construction and subsequent use of the instrument; in consequence of which, the variations in the temperature of the air, though they produce their full effects on the instrument, as a thermometer, do not interfere with or embarrass its indications as an hygrometer.

17. In the Philos. Trans. for 1791, Mr. Deluc has given a second paper on hygrometry. This has been chiefly occasioned by a memoir of M. de Saussure on the same subject, entitled *Essais sur l'Hygrométrie*, in 4to, 1783. In this work M. de S. describes a new hygrometer of his construction, on the following principle.—It is a known fact that a hair will stretch when it is moistened, and contract when dried: and M. de Saussure found, by repeated experiments, that the difference between the greatest extension and contraction, when the hair is properly prepared, and has a weight of about 3 grains suspended by it, is nearly one-40th of its whole length, or one inch in 40. This circumstance suggested the idea of a new hygrometer. To render these small variations of the length of the hair perceptible, an apparatus was contrived, in which one of the extremities of the hair is fixed, and the other, bearing the counterpoise abovementioned, surrounds the circumference of a cylinder, which turns upon an axis to which a hand is adapted, marking upon a dial in large divisions the almost insensible motion of this axis. About 12 inches high is recommended as the most convenient and useful: and to render them portable, a contrivance is added, by which the hand and the counterpoise can be occasionally fixed.

But, for all the reasonings of these ingenious philosophers on this interesting subject, and complete information, see the Philos. Trans. an. 1791, pa. 1, and 389; and Deluc's Meteorologie, vol. 1, an. 1786; as also the Monthly Review, vol. 51, pa. 224, vol. 71, pa. 213, vol. 76, pa. 316, vol. 78, pa. 236, and vol. 6, of the new series for the year 1791, pa. 133.

HYGROMETRY, the science of the measurement of the moisture of the atmosphere. The chief writings on this science are those of M. Deluc and M. de Saussure, for which see the last article.

HYGROSCOPE, is commonly used in the same sense with Hygrometer. Wolfius, however, regarding the etymology of the word, makes some difference. According to him, the hygroscope only shows that there are alterations of the air in respect of humidity and dryness, but

the hygrometer measures them. A hygroscope therefore is only an indefinite or less accurate hygrometer.

HYPATIA, a very learned and beautiful lady, was born at Alexandria, about the end of the 4th century, as she flourished about the year of Christ 430. She was the daughter of Theon, a celebrated philosopher and mathematician, and president of the famous Alexandrian school. Her father, encouraged by her extraordinary genius, had her not only educated in all the ordinary accomplishments of her sex, but instructed in the most abstruse sciences. She made such great progress in philosophy, geometry, astronomy, and the mathematics in general, that she passed for the most learned person of her time. She published commentaries on Apollonius's Conics, on Diophantus's Arithmetic, and other works. At length she was thought worthy to succeed her father in that distinguished and important employment, the government of the school of Alexandria; and to deliver instructions out of that chair where Ammonius, Hierocles, and many other great men, had taught before; and this at a time when men of great learning abounded both at Alexandria and in many other parts of the Roman empire. Her fame being so extensive, and her worth so universally acknowledged, it was no wonder that she had a crowded auditory. "She explained to her hearers (says Socrates, an ecclesiastical historian of the 5th century, born at Constantinople) the several sciences that go under the general name of philosophy; for which reason there was a confluence to her; from all parts, of those who made philosophy their delight and study."

The pupils of this lovely and surprising female, were not less eminent than they were numerous. One of them was the celebrated Synesius, who was afterwards bishop of Ptolemais. This ancient Christian Platonist always expresses the strongest, as well as the most grateful testimony of the virtue of his tutress; never mentioning her without the most profound respect, and sometimes in terms of affection, but little short of adoration. But it was not Synesius only, and the disciples of the Alexandrian school, who admired Hypatia for her virtue and learning: never was woman more caressed by the publick, and yet never had woman a more unspotted character. She was held as an oracle for her wisdom, for which she was consulted by the magistrates in all important cases; a circumstance which often drew her among the greatest concourse of men, without the least censure of her manners. In short, when Nicephorus intended to pass the highest compliment on the princess Endocia, he thought he could not do it better than by calling her another Hypatia.

While Hypatia thus reigned the brightest ornament of Alexandria, Orestes was governor of that place for the emperor Theodosius, and Cyril was bishop or patriarch. Orestes, having had a liberal education, could not but admire Hypatia; and as a wise governor often consulted her. This, together with an aversion which Cyril had against Orestes, proved fatal to the lady. About 500 monks assembling, attacked the governor one day, and would have killed him, had he not been rescued by the townsmen; and the respect which Orestes had for Hypatia causing her to be traduced among the Christian multitude, they dragged her from her chair, tore her in pieces, and burnt her limbs. This horrible catastrophe was perpetrated during the lent of the year 416.

Cyril is strongly suspected of having fomented this tragedy. Cave indeed endeavours to remove the imputation

of so horrid an action from the patriarch; and places it on the Alexandrian mob in general, whom he calls "a very trifling inconstant people." But though Cyril should be allowed neither to have been the perpetrator, nor even the contriver of it, yet it is much to be suspected that he did not disown it in the manner he ought to have done: a suspicion which must needs be greatly confirmed by reflecting, that he was so far from censuring the violence committed by the monks upon Orestes, that he afterwards received the dead body of Ammonius, one of the most conspicuous in that brutality, who had grievously wounded the governor, and who was justly punished with death. Upon this riotous ruffian, Cyril made a panegyric in the church where he was laid, in which he extolled his courage and constancy, as one that had contended for the truth; and changing his name to Thaumasius, or the Admirable, ordered him to be considered as a martyr. "However (continues Socrates), the wisest part of Christians did not approve the zeal which Cyril showed on this man's behalf, being convinced that Ammonius had justly suffered for his desperate attempt."

HYPERBOLA, one of the conic sections, being that which is made by a plane cutting a cone, so that, entering one side of the cone, and not being parallel to the opposite side, it may cut the circular base when the opposite side is ever so far produced below the vertex, or shall cut the opposite side of the cone produced above the vertex, or shall make a greater angle with the base than the opposite side of the cone makes; all these three circumstances amounting to the same thing, but in other words.

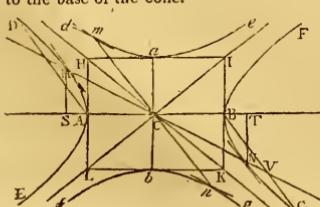

1. Thus, the figure DAE is an hyperbola, made by a plane entering the side VQ of a cone PVQ at A , and either cutting the base PQ when the plane is not parallel to VP , and this is ever so far produced; or when the angle ARQ is greater than the angle VHQ ; or when the plane cuts the opposite side in B above the vertex.

2. By the hyperbola is sometimes meant the whole plane of the section, and sometimes only the curve line of the section.

3. Hence, the cutting plane meets the opposite cone in B , and there forms another hyperbola DBE , equal to the former one, and having the same transverse axis AB ; and the same vertices A and B . Also the two are called Opposite Hyperbolae.

4. The centre c is the middle of the transverse axis.

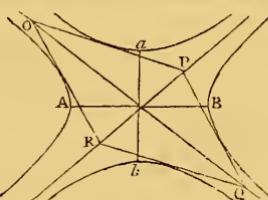

5. The semi-conjugate axis is cl , a mean proportional between cr and ck , the distances to the sides of the opposite cone, when cr is drawn parallel to the diameter PQ of the base of the cone. Or the whole conjugate axis is a mean proportional between AF and BH , which are drawn parallel to the base of the cone.

6. If DAE and FBG be two opposite hyperbolae, having the same transverse and conjugate axes AB and ab , perpendicularly bisecting each other; and if dfe and fbg be two other opposite hyperbolae, having the same axes with the two former, but in the contrary order, viz, having ab for their first or transverse axis, and $a'b$ for their second or conjugate axis; then any two adjacent curves are called Conjugate Hyperbolae, and the whole figure formed by all the four curves, the figure of the Conjugate Hyperbolae. And if the rectangle $HIKL$ be inscribed within the four conjugate hyperbolae, touching the vertices A, B, a, b , and having their sides parallel and equal to the two axes; and if then the two diagonals HK , IC , of the parallelogram be drawn, these diagonals are the asymptotes of the curves, being lines that continually approach nearer and nearer to the curves, without meeting them, except at an infinite distance, where each asymptote and the two adjacent sides of the two conjugate hyperbolae may be supposed all to meet; the asymptote being there a common tangent to them both, viz, at that infinite distance.

7. Hence the four hyperbolae, meeting and running into each other at the infinite distance, may be considered as the four parts of one entire curve, having the same axes, tangents, and other properties.

8. A diameter in general, is any line, as MN , drawn through the centre c , and meeting, or terminated by, the opposite legs of the opposite hyperbolae. And if parallel to this diameter there be drawn two tangents, at m and n , to the opposite legs of the other two opposite hyperbolae, the line mcn joining the points of contact, is the conjugate diameter to MN , and the two mutually conjugates to each other. Or, if to the points m or n there be drawn a tangent, and through the centre c the line mc parallel to it, that line will be the conjugate to MN . The points where each of these meets the curves, as M, N, m, n , are the vertices of the diameters; and the tangents to the curves at the two vertices of any diameter, are parallel to each other, and also to the other or conjugate diameter.

9. Moreover, if those tangents to the four hyperbolae, at the vertices of two conjugate diameters, be produced till they meet, they will form a parallelogram $OPQR$; and the diagonals oq and pr of the parallelogram will be the asymptotes of the curves; which therefore pass through the opposite angles of all the parallelograms so inscribed between the curves. Also it is a property of these parallelograms, that they are all equal to each other, and therefore equal to the rectangle of the two axes; as will be further noticed below. Further, if these diagonals or asymptotes make a right angle between them, or if the inscribed parallelogram be a square, or if the two axes be equal to each other, then the hyperbola is called a right-angled or an equilateral one.

10. An ordinate to any diameter, is a line drawn parallel to its conjugate, or to the tangent at its vertex, and terminated by the diameter produced and the curve. So MS and TN are ordinates to the axis AB ; also AD and BG are ordinates to the diameter MN (last fig. but one). Hence the ordinates to the axis are perpendicular to it; but ordinates to the other diameters are oblique to them.

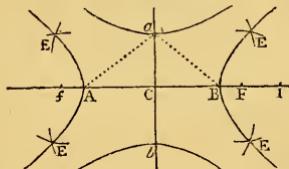

11. An absciss is a part of any diameter, contained between its vertex and an ordinate to it; and every ordinate has two abscissas: as AT and BT , or MV and NV .

12. The parameter of any diameter, is a third proportional to the diameter and its conjugate.—The parameter of the axis is also equal to the line AG or ng (fig. 1), if rg be drawn to make the angle $AFg =$ the angle BAv , or the line ng to make the angle $ngn =$ the angle ABv .

13. The focus is the point in the axis where the ordinate is equal to half the parameter of the axis; as s and t (fig. 2) if MS and TN be half the parameter, or the 3d proportional to ca and ca . Hence there are two foci, one on each side the vertex, or one for each of the opposite hyperbolas. These two points in the axis are called foci, or burning points, because it is found by opticians that rays of light issuing from one of them, and falling upon the curve of the hyperbola, are reflected into lines that verge towards the other point or focus.

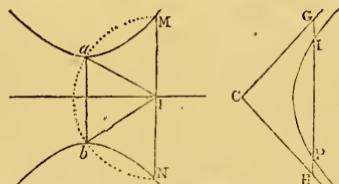

To describe an Hyperbola, in various ways.

14. (1st Way by points.)—In the transverse axis AF produced, take the foci r and f , by making $CF = cf = aa$ or ba , assume any point i : Then with the

radii AI , BI , and centres r , f , describe arcs intersecting in E , which will give two points in each of the opposite curves EAE' , EDE' . In like manner, assuming other points i , as many other points will be found in the curve. Then, with a steady hand, draw the curve line through all the points of intersection E .—In the same manner are to be constructed the other pair of opposite hyperbolas, using the axis ab instead of AB .

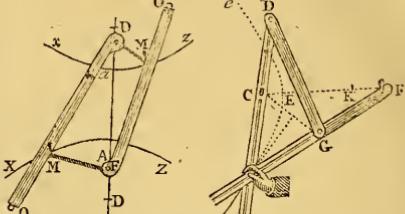

15. (2d Way by points, for a Right-angled Hyperbola only.)—On the axis produced if necessary, take any

point i , through which draw a perpendicular line, upon which set off IM and IN , equal to the distance ia or ib , from i to the extremities of the other axis; and M and N will be points in the curve.

16. (3d Way by points, to describe the curve through a given point.)— CG and CH being the asymptotes, and P the given point of the curve; through the point P draw any line GPH between the asymptotes, upon which take $GP = PH$, so shall I be another point of the curve. And in this manner may any number of points be found, drawing as many lines through the given point P .

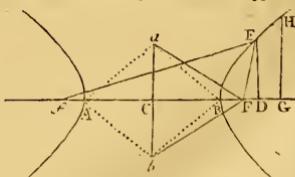

17. (4th Way by a continued Motion.)—If one end of a

long ruler fMO be fastened at the point f , by a pin on a plane, so as to turn freely about that point as a centre. Then take a thread FMO , shorter than the ruler, and fix one end of it in F , and the other to the end o of the ruler. Then if the ruler fMO be turned about the fixed point f , at the same time keeping the thread omf always tight, and its part mo close to the side of the ruler, by means of the pin M ; the curve line AX described by the motion of the pin M is one part of an hyperbola. And if the ruler be turned, and move on the other side of the fixed point f , the other part AZ of the same hyperbola may be described after the same manner.—But if the end of the ruler be fixed in F , and that of the thread in f , the opposite hyperbola xaz may be described.

18. (5th Way, by a continued Motion.)—Let c and r be the two foci, and E and K the two vertices of the hyperbola. (See the last fig. above.) Take three rulers cd , dg , gf , so that $cd = gf = ek$, and $dg = cf$; the rulers cd and gf being of an indefinite length beyond c and g , and having slits in them for a pin to move in; and the rulers having holes in them at c and r , to fasten them to the foci c and r by means of pins, and at the points d and g they are to be joined by the ruler dg . Then, if a pin be put in the slits, viz, the common intersection of the rulers cd and gf , and moved along, causing the two rulers gr , cd , to turn about the foci c and r , that pin will describe the portion EE' of an hyperbola.—The foregoing are a few among various ways given by several authors.

Some of the chief Properties of the Hyperbola.

19. (1st) The squares of the ordinates, of any diameter, are to each other, as the rectangles of their abscissas; i. e. $DE^2 : GH^2 :: AD : BD : AG : BG$.

20. As the square of any diameter, is to the square of its conjugate; so is the rectangle of two abscissas, to the

square of their ordinate. That is, $AB^2 : ab^2 :: AD \cdot BD : DE^2$.

Or, because the rectangle $AD \cdot BD$ is = the difference of the squares $CD^2 - CB^2$, the same property is,

$$\text{As } AB^2 : ab^2 :: CD^2 - CB^2 : DE^2,$$

$$\text{Or } AB : \frac{ab^2}{AB} :: CD^2 - CB^2 : DE^2,$$

That is $AB : p :: CD^2 - CB^2 : DE^2$, where p is the parameter of the diameter AB , or the 3d proportional to AB and ab , or $\frac{ab^2}{AB}$.

And hence is deduced the common equation of the hyperbola, by which its general nature is expressed. Thus, putting d = the semidiameter CA or CN ,

$$c = \text{its semiconjugate } ca \text{ or } cb,$$

$$p = \text{its parameter or } \frac{2d^2}{c},$$

x = the absciss BD from the vertex,

y = the ordinate DE , and

v = the absciss CD from the centre:

Then is $d^2 : c^2 :: (2d + x) : y^2$,

$$\text{or } d^2 : c^2 :: (d + v) : y^2,$$

$$\text{or } d^2 : c^2 :: v^2 - d^2 : y^2,$$

$$\text{or } d : p :: v^2 - d^2 : y^2; \text{ so that}$$

$$y^2 = \frac{2dc + x^2}{d^2} \cdot c^2 = \frac{v^2 - d^2}{d^2} \cdot c^2 = \frac{v^2 - d^2}{d} \cdot p; \text{ any}$$

of which equations or proportions express the nature of the curve. And hence arises the name hyperbola, signifying to exceed, because the ratio of d^2 to c^2 , or of d to p , exceeds that of $2dc$ to y^2 ; that ratio being equal in the parabola, and defective in the ellipse, from which circumstances these also take their names.

21. The distance between the centre and the focus, is equal to the distance between the extremities of the transverse and conjugate axes. That is, $CF = aa$ or Ab , where F is the focus.

22. The conjugate semi-axis is a mean proportional between the distances of the focus from both vertices of the transverse. That is, ca is a mean between AF and BF , or $AP : CA :: CA : BF$, or $AF : BF = CA^2$.

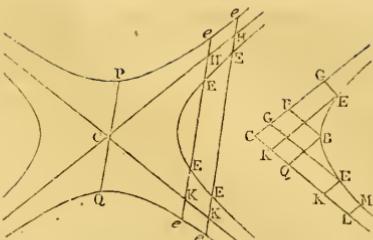

23. The difference of two lines drawn from the foci, to meet in any point of the curve, is equal to the transverse axis. That is, $FE - FE = AB$, where F and f are the two foci.

24. All the parallelograms inscribed between the four conjugate hyperbolae are equal to one another, and therefore each equal to the rectangle of the two axes. That is, the parallelogram $OQPR = AB \cdot ab$ (fig. to art. 9).

25. The difference of the squares of every pair of conjugate diameters, is equal to the same constant quantity, viz, the difference of the squares of the two axes. That is, $MN^2 - MN^2 = AB^2 - ab^2$, (fig. to art. 6) where MN and mn are any two conjugate diameters.

26. The rectangles of the parts of two parallel lines, terminated by the curve, are to each other, as the rectangles of the parts of any other two parallel lines, any where cutting the former. Or the rectangles of the parts of two intersecting lines, are as the squares of their parallel diameters, or squares of their parallel tangents.

27. All the rectangles are equal which are made of the segments of any parallel lines, cut by the curve, and limited by the asymptotes, and each equal to the square of their parallel diameter. That is, $HE \cdot EK$ or $he \cdot ek = cq^2$ or cp^2 .

28. All the parallelograms are equal, which are formed between the asymptotes and curve, by lines parallel to the asymptotes. That is, the paral. $COEK = CPBQ$.—Hence is obtained another method of expressing the nature of the curve by an equation, involving the absciss taken on one asymptote, and ordinate parallel to the other asymptote. Thus, if $x = CR$, $y = KE$, $a = co$, and $b = bq$ the ordinate at the vertex B of the curve; then, by the property in this article, $ab = xy$, or $a : x :: y : b$; that is, the rectangle of the absciss and ordinate is every where of the same magnitude, or any ordinate is reciprocally as its absciss.

29. If the absciss cq , ck , cl , &c., taken on the one asymptote, be in geometrical progression increasing; then shall the ordinates qb , ke , lm , &c., parallel to the other asymptote, be a like geometrical progression in the same ratio, but decreasing; and all the rectangles are equal, under every absciss and its ordinate, viz, $cq \cdot qb = ck \cdot ke = cl \cdot lm$, &c.

30. The absciss cq , ck , cl , &c., being taken in geometrical progression; the spaces or asymptotic areas $BQKE$, $EKLM$, &c., will be all equal; or, the spaces $BQKE$, $BQLM$, &c., will be in arithmetical progression; and therefore these spaces are the hyperbolic logarithms of those absciss.

These, and many other curious properties of the hyperbola, may be seen demonstrated in my Treatise on Conic Sections, and several others. See also CONIC SECTIONS.

Acute HYPERBOLA, one whose asymptotes make an acute angle.

Ambigual HYPERBOLA, is that which has one of its infinite legs falling within an angle formed by the asymptotes, and the other falling without that angle. This is one of Newton's triple hyperbolae of the 2d order. See his *Emendatio Lin. tert. Ord.* See also AMBIGENAL.

Common, or Conic HYPERBOLA, is that which arises from the section of a cone by a plane; called also the Apollonian hyperbola, being that which was treated on by the first and chief author Apollonius.

Conjugate HYPERBOLAS, are those formed or lying together, and having the same axes, but in a contrary order, viz, the transverse of each equal the conjugate of the other; as the two Conjugate Hyperbolae pee and eee in the last figure but one.

Equilateral, or Rectangular HYPERBOLA, is that whose two axes are equal to each other, or whose asymptotes make a right angle.—Hence, the property or equation of the equilateral hyperbola, is $y^2 = ax + x^2$, where a is the axis, x the absciss, and y its ordinate; which is similar to the equation of the circle, viz, $y^2 = ax - x^2$, differing only in the sign of the second term, and where a is the diameter of the circle.

Infinite HYPERBOLAS, or HYPERBOLAS of the higher kinds, are expressed or defined by general equations similar

to that of the conic or common hyperbola, but having general exponents, instead of the particular numeral ones, but so as that the sum of those on one side of the equation, is equal to the sum of those on the other side. Such as, $ay^m + n = bx^m(d + x)^n$, where x and y are the absciss and ordinate to the axis or diameter of the curve; or $x^m y^n = a^m + n$, where the absciss x is taken on one asymptote, and the ordinate y parallel to the other.

As the hyperbola of the first kind, or order, viz the conic hyperbola, has two asymptotes; that of the 2d kind or order has three; that of the 3d kind, four; and so on.

Obtuse HYPERBOLA, is that whose asymptotes form an obtuse angle.

Opposite HYPERBOLAS, are those, *pee*, *qee*, having the same transverse and conjugate axes.

Rectangular HYPERBOLA, the same as equilateral hyperbola.

HYPERBOLIC Arc, is the arc of an hyperbola.

Put $a = ca$ the semitransverse axe, $c = ca$ the semiconjugate, $y =$ an ordinate pq to the axe drawn from the end q of the arc AQ , beginning at the vertex A : then putting $q = \frac{aa + cc}{c^2}$,

$$\Delta = \text{the hyp. log. of } \frac{y + \sqrt{(cc + yy)}}{c}$$

$$= 2.302585093 \times \text{common log. of } \frac{y + \sqrt{(cc + yy)}}{c}, \quad B = \frac{y\sqrt{(cc + yy)} - cc}{2}, \quad c =$$

$$\frac{y^2\sqrt{(cc + yy)} - 3ccB}{4}, \quad \&c; \text{ then is the length of the arc } AQ$$

expressed by $c \times (\Delta + \frac{q}{2}B - \frac{q^2}{24}c + \frac{1.3q^3}{24.6}D - \frac{1.3q^4}{24.6}E \&c;$ or by $\frac{15c^2t + (21c^2 + 19t^2)x}{15c^2t + (21c^2 + 9t^2)x} \times y$, nearly; where t is the whole transverse axe $2ca$, $c = 2ca$ the conjugate, $x = AP$ the absciss, and $y = pq$ the ordinate.

These and other rules may be seen demonstrated in my Mensuration, pa. 310 and 313, 4th edit.

HYPERBOLIC Area, that included by the hyperbolic curve and other lines.

Putting $a = ca$ the semitransverse, $c = ca$ the semiconjugate, $y = pq$ the ordinate, and $v = cr$ its distance from the centre; then is the

$$\text{area } APQ = \frac{1}{2}vy - \frac{1}{2}ac \times \text{hyp. log. of } \frac{ay + cv}{ac};$$

$$\text{sector } CAQ = \frac{1}{2}ac \times \text{hyp. log. of } \frac{ay + cv}{ac};$$

$$\text{area } APQ = 2xy \times \left(\frac{1}{3} - \frac{z^1}{1.3.5} - \frac{z^2}{3.5.7} - \frac{z^3}{5.7.9} - \frac{z^4}{7.9.11} \&c \right),$$

$$\text{where } x = AP, \text{ and } z = \frac{x}{2a + x}; \text{ or}$$

$$APQ = \frac{2x}{15a} \times [\sqrt{2ax} + 4\sqrt{(2ax + \frac{3}{4}xx)}] \text{ nearly.}$$

Let ct and cr be the two asymptotes, and the ordinates DA , EF parallel to the other asymptote ct ; then the asymptotic space $ADEF$ or sector CAF is

$$= cd \times DA \times \text{hyp. log. of } \frac{ce}{ct}, \text{ or}$$

$$= cd \times DA \times \text{hyp. log. of } \frac{da}{ef}, \text{ or}$$

$$= cd \times DA \times \frac{de}{cd} - \frac{de^2}{2cd^2} + \frac{de^3}{3cd^3} - \frac{de^4}{4cd^4} \&c; \text{ and this last series was first given by Mercator in his Logarithmotechnia.}$$

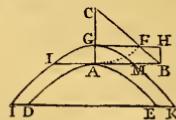

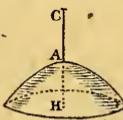

See my Mensuration, pa. 315, &c, 4th edit.

Generally, if $x^m y^n = a^m + n$ be an equation expressing an hyperbola of any order; then its asymptotic area will be $\frac{n}{n-m} xy$; which space therefore is always quadable, in all the orders of hyperbolas, except the first or common hyperbola only, in which m and n being each 1, the denominator $n - m$ becomes 0 or nothing.

HYPERBOLIC Conoid, a solid formed by the revolution of an hyperbola about its axis, otherwise called an hyperboloid.

To find the Solid Content of an Hyperboloid.

Let AC be the semitransverse of the generating hyperbola, and AH the height of the solid; then as $2AC + AH$ is to $3AC + AH$, so is the cone of the same base and altitude, to the content of the conoid.

To find the Curve Surface of an Hyperboloid.

Let AC be the semitransverse, and AB perpendicular to it, and equal to the semiconjugate of ADE the generating hyperbola, or section through the axis of the solid. Join CB ; make $CF = ca$, and on CA let fall the perpendicular FG ; then with the semitransverse CG , and semiconjugate $GH = AB$, describe the hyperbola GIR ; then as the diameter of a circle is to its circumference, so is the hyperboloid frustum $ILAMK$ to the curve surface of the conoid generated by DAE . See my Mensur. pa. 328, &c, 4th edit.

HYPERBOLIC Cylindroid, a solid formed by the revolution of an hyperbola about its conjugate axis, or line through the centre perpendicular to the transverse axis. This solid is treated of in the Phil. Trans. by Sir Christopher Wren, who shows some of its properties, and applies it to the grinding of hyperbolical glasses; affirming that they must be formed this way, or not at all. See Philos. Trans. vol. 4, pa. 961.

HYPERBOLIC Leg, of a curve, is that having an asymptote, or tangent at an infinite distance. Newton reduces all curves, both of the first and higher kinds, into hyperbolic and parabolic legs, i.e. such as have asymptotes, and such as have not, or such as have tangents at an infinite distance, and such as have not.

HYPERBOLIC Line, is used by some authors for what is more commonly called the hyperbola itself, being the curve line of that figure; in which sense the surface terminated by it is called the hyperbola.

HYPERBOLIC Logarithm, a logarithm so called as being similar to the asymptotic spaces of the hyperbola. The hyperbolic logarithm of a number, is to the common logarithm, as 2.3025850929940457 to 1, or as 1 to 4342944819032518 . The first invented logarithms, by Napier, are of the hyperbolic kind; and so are Kepler's. See LOGARITHM.

HYPERBOLIC Mirror, is one ground into that shape.

HYPERBOLIC Space, the same as Hyperbolic Area.

HYPERBOLICUM Acutum, a solid made by the revolution of the infinite area or space contained between the curve of the hyperbola, and its asymptote. This produces a solid, which though infinitely long and gene-

rated by an infinite area, is nevertheless equal to a finite solid body; as is denominated by Torricelli, who gave it this name.

HYPERBOLIFORM Figures, are such curves as approach, in their properties, to the nature of the hyperbola; called also hyperboloides.

HYPEROLOIDS, are hyperolas of the higher kind, whose nature is expressed by this equation, $ay^m + n = bx^m(a + x)^n$. See HYPERBOLA. It also means the hyperbolic conoid. See that article.

HYPEROBOREANS, the most northern nations, or regions, as dwelling beyond or about the wind Boreas: as the Siberians, Samoieds, &c.

HYPERTHYRON, in Architecture, a sort of table, usually placed over gates or doors of the Doric order, above the chambranle, in form of a frieze.

HYPETHRE, in Ancient Architecture, two rows of pillars surrounding, and ten at each face of a temple, &c, with a peristyle within of six columns.

HYPOGEUM, in the Ancient Architecture, a name common to all the parts of a building that are under ground; as the cellars, butteries, &c.

HYPOMOCHLION, the fulcrum or prop of a lever; or the point which sustains its pressure, when employed either in raising or lowering bodies. The hypomochlion is frequently a roller set under the lever; or under stones or pieces of timber, &c, that they may be the more easily lifted up, or removed.

HYPOTENUSE, or **HYPOTHENUSE**, in a right-angled triangle, is the side which subtends, or is opposite to the right angle, being always the longest of the three sides; as the side AC , opposite to the right angle B .

It is a celebrated theorem in plane geometry, being the 47th prop. of the 1st book of Euclid, that in every right-angled triangle ABC , the square formed on the hypotenuse AC , is equal to both the two squares formed upon the other two sides AB and BC ; or that $AC^2 = AB^2 + BC^2$. This is particularly called

the Pythagorean theorem, from its reputed inventor, Pythagoras, who it is said sacrificed a whole hecatomb to the muses, in gratitude for the discovery. But the same thing is true of circles or any other similar figures, viz, that any figure described on the hypotenuse, is equal to the sum of the two similar figures described on both the other two sides.

HYPOTHENUSE. See HYPOTENUSE.

HYPOTHESIS, in Geometry, or Mathematics, means much the same thing with supposition, being an assumption of something as a condition, upon which to raise a demonstration, or from which to draw an inference.

Hypotheses, or postulatums, are considered by Dr. Barrow as propositions assuming or affirming some evi-

dently possible mode, action, or motion of a thing, and that there is the same affinity between hypotheses and problems, as between axioms and theorems: a problem showing the manner, and demonstrating the possibility of some structure, and an hypothesis assuming some construction which is manifestly possible.

In disputation, false hypotheses are often employed in order to draw the antagonists into absurdities; and even in geometry, truths are often to be deduced from such false hypotheses.

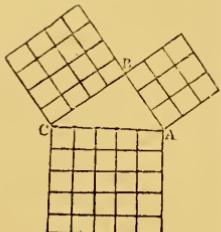

Every conditional, or hypothetical proposition, may be distinguished into hypothesis and thesis: the first asserts the conditions under which any thing is affirmed or denied; and the latter is the thing itself affirmed or denied. Thus, in the proposition, a triangle is half of a parallelogram, if the bases and altitudes of the two be equal; the latter part, namely, "if the bases," &c, is the hypothesis; and the former part, "a triangle is half a parallelogram," the thesis.

In strict logic, we are never to pass from the hypothesis to the thesis: that is, the principle supposed must be proved to be true, before we require the consequence to be made.

HYPOTHESIS, in Philosophy, denotes a kind of system laid down from our own imagination, by which to account for some phenomenon or appearance of nature. Thus, there are hypotheses to account for the tides, for gravity, for magnetism, for the deluge, &c. The real and scientific causes of natural things generally lie very deep in obscurity: observation and experiment, the proper means of arriving at them, are in most cases extremely slow; and the human mind in consequence gets very impatient: hence we are often induced to feign or invent something that may seem like the cause, and which is calculated to answer the several phenomena, so that it may possibly be the true cause. Philosophers are divided as to the use of such fictions or hypotheses, which are much less current now than they were formerly. The latest and best writers are for excluding hypotheses, and standing entirely on observation and experiment. Whatever is not deduced from phenomena, says Newton, is an hypothesis; and hypotheses, whether metaphysical, or physical, or mechanical, or of occult qualities, have no place in experimental philosophy. Phil. Nat. Prin. Math. in Calc.

HYPOTHESIS is more particularly applied, in astronomy, to the several systems of the heavens; or the divers manners in which different astronomers have supposed the heavenly bodies to be ranged, or moved. The principal hypotheses are the Ptolemaic, the Tychonic, and the Copernican. This last is now so generally received, and so well established and warranted by observation, that it is thought derogatory to it to call it an hypothesis.

HYPOTRACHELION, in Architecture, is used for a little frieze in the Tuscan and Doric capital, between the astragal and annulets; called also the colcrin and gorgerin. The word is applied by some authors in a more general sense, to the neck of any column, or that part of its capital below the astragal.

I. J.

JACK, in Mechanics, is an instrument in common use for raising heavy timber, or very great weights of any kind; being a certain powerful combination of teeth and pinions; the whole inclosed in a strong wooden stock or frame *BC*, and moved by a winch or handle *MP*; the outside appearing as in the figure annexed.

In fig. 6, pl. 14, the wheel or rack-work is shown, being the view of the inside when the stock is removed. Though it is not drawn in the just proportions and dimensions, for the rack *AB* must be supposed at least four times as long in proportion to the wheel *Q*, as the figure represents it; and the teeth, which will be then four times more in number to have about 3 in the inch. Now if the handle *MP* be 7 inches long, the circumference of this radius will be 44 inches, which is the distance or space the power moves through in one revolution of the handle; but as the pinion of the handle has but 4 leaves, and the wheel *Q* suppose 20 teeth, or 5 times the number, therefore to make one revolution of the wheel *Q*, it requires 5 turns of the handle, in which case it passes through 5 times 44 or 220 inches: but the wheel having a pinion *R* of 3 leaves, these will raise the rack 3 teeth, or one inch, in the same space. Hence then, the handle or power moving 220 times as fast as the weight, will raise or balance a weight of 220 times its own power. And if this be the hand of a man, who can sustain 100 pounds weight, he will, by help of this jack, be able to raise, or sustain a weight or force of 22000lb, or about 10 tons weight. This machine is sometimes open behind from the bottom almost up to the wheel *Q*, to let the lower claw, which in that case is turned up at *n*, raise any weight. When the weight is drawn or pushed sufficiently high, it is kept from going back by hanging the end of the hook *s*, fixed to a staple, over the curved part of the handle at *h*.

JACK is also the name of a well-known engine in the kitchen, used for turning a spit. Here the weight is the power applied, acting by a set of pulleys; the friction of the parts, and the weight with which the spit is charged, make the force to be overcome; and a steady uniform motion is maintained by means of the fly. See the fig. of this machine, pl. 14, fig. 7.

Smoke JACK, is an engine used for the same purpose with the common jack, and is so called from its being moved by means of the smoke, or rarefied air, ascending the chimney, and striking against the sails of the horizontal wheel *AB* (plate 14, fig. 8), which being inclined to the horizon, is moved about the axis of the wheel, together with the pinion *C*, which carries the wheels *D* and *E*; and *E* carries the chain *V*, which turns the spit. The wheel *AB* should be placed in the narrow part of the chimney, where the motion of the smoke is swiftest, and where also

the greatest part of it must strike on the sails. The force of this machine depends upon the draught of the chimney, and the strength of the fire.

JACK-Arch, is an arch of one brick thickness.

JACK-HEAD, a part sometimes annexed to the forcing pump.

JACOB'S-STAFF, a mathematical instrument for taking heights and distances; the same with the Cross-staff; which see.

JAMBS, or **JAUMS**, in Architecture, are the upright sides of chimneys, from the hearth to the mantle-tree. Also door posts, or the upright posts at the ends of the window frames.

St. JAMES'S Day, a festival in the calendar, observed on the 25th of July, in honour of St. James the apostle.

JANUARY, the first month of the year, according to the computation now used in the West, and containing 31 days; so called by the Romans from Janus, one of their divinities, to whom they gave two faces; because on the one side, the first day of this month looked towards the new year, and on the other towards the old one. The name may also be derived from Janua, a gate; this month, being the first of the year, may be considered as the gate or entrance of it. January and February were introduced into the year, by Numa Pompilius; Romulus's year beginning with the month of March.

JAUMS. See **JAMBS**.

ICE, a brittle transparent body, formed of some fluid, frozen or fixed by cold. The specific gravity of ice to water, is various, according to the nature and circumstances of the water, degree of cold, &c. Dr. Irving (Phipps's Voyage towards the North Pole) found the densest ice he could meet with about a 14th part lighter than water. M. de Mairan found it, at different trials, 1-14th, 18th, or 19th lighter than water; and when the water was previously purged of air, only a 22d part.

The rarefaction of ice has been supposed owing to the air-bubbles produced in ice while freezing; these, being considerably large in proportion to the water frozen, render the ice so much specifically lighter. It is well known that a considerable quantity of air is lodged in the interstices of water, though it has there little or no elastic property, on account of the disunion of its particles; but on these particles coming closer together, and uniting as the water freezes, light, expansive, and elastic air-bubbles are thus generated, and increase in bulk as the cold grows stronger, and by their elastic force bursts to pieces any vessel in which the water is closely contained. But snow-water, or any water long boiled over the fire, affords an ice more solid, and with fewer bubbles. Pure water long kept in vacuo and frozen afterwards, freezes much sooner, on being exposed to the same degree of cold, than water unpurged of its air and set in the open atmosphere. And the ice made of water thus divested of its air, is much harder, more solid and transparent, and heavier than common ice.

But M. de Mairan, in a dissertation on ice, attributes the increase of the bulk of the water under this form,

chiefly to a different arrangement of its parts: the icy skin on water being composed of filaments which are found to be joined constantly and regularly at an angle of 60° , and which, by this disposition, occupy a greater volume than if they were parallel. Besides, after ice is formed, he found it continue to expand by cold; a piece of ice, which was at first only a 14th part specifically lighter than water, on being exposed some days to the frost, became a 12th part lighter; and thus he accounts for the bursting of ice in ponds.

It appears from an experiment of Dr. Hooke, in 1663, that ice refracts the light less than water; whence he infers, that the lightness of ice, which causes it to swim in water, is not produced merely by the small bubbles which are visible in it, but that it arises from the uniform constitution or general texture of the whole mass: a fact which was afterwards confirmed by M. Lahire. See Hooke's Exper. by Derham, pa. 26, Acad. Per. 1693, Mem. pa. 25.

Sir Robert Barker thus describes the process of making ice in the East Indies, in a country where he never saw any natural ice. On a large plain is dug three, or four pits, each about 30 feet square, and 2 feet deep; the bottoms of which are covered, about 8 or 12 inches thick, with sugar-cane, or the stems of the large Indian corn, dried. On this bed are placed in rows a number of small shallow unglazed earthen pans, formed of a very porous earth, a quarter of an inch thick, and about an inch and a quarter deep; which, at the dusk of the evening, they fill with soft water that has been boiled. In the morning before sunrise the ice-makers attend at the pits, and collect what has been frozen in baskets, which they convey to the place of preservation. This is usually prepared in some high and dry situation, by sinking a pit 14 or 15 feet deep, which they line first with straw, and then with a coarse kind of blanketing. The ice is deposited in this pit, and beaten down with rammers, till at length its own accumulated cold again freezes it, and it forms one solid mass. The mouth of the pit is well secured from the exterior air with straw and blankets, and a thatched roof is thrown over the whole. Philos. Trans. vol. 65, pa. 252.

For the force of ice and other very interesting particulars relating to it, see the articles FREEZING, COLD, and CONGELATION.

ICHNOGRAPHY, in Architecture, is a transverse or horizontal section of a building, exhibiting the plot of the whole edifice, and of the several rooms and apartments in any story; together with the thickness of the walls and partitions; the dimensions of the doors, windows, and chimneys; the projectures of the columns and piers, with every thing visible in such a section.

ICHNOGRAPHY, in Fortification, is the plan or representation of the length and breadth of a fortress; the distinct parts of which are marked out, either on the ground itself, or upon paper.

ICHNOGRAPHY, in Perspective, the view of any thing cut off by a plane parallel to the horizon, just by the base or bottom of it; being the same with what is otherwise called the plan, geometrical plan, or ground-plot, of any thing, and is opposed to Orthography or Elevation.

ICOSAEDRON, or ICOSAHEDRON, one of the five regular bodies or solids, terminated by twenty equilateral and equal triangles. It may be considered as consisting of 20 equal and similar triangular pyramids, whose vertices meet in the centre of a sphere conceived to circum-

scribe it, and therefore having all their heights and bases equal: hence the solidity of one of those pyramids multiplied by 20, the number of them, gives the solid content of the icosaedron.

To form or make the Icosaedron.—Describe upon a card paper, or some other such like substance, 20 equilateral triangles, as in the figure at the article Regular Body. Cut it out by the extreme edges, and cut all the other lines half through, then fold the sides up by these edges, and the solid will be formed.

The linear edge or side of the icosaedron being A , then will the surface be $5 A^2 \sqrt{3} = 8.6602540 A^2$, and the solidity = $\frac{5}{6} A^3 \sqrt{7 + 3\sqrt{5}} = 2.1816950 A^3$.

More general equations, and relations, may be seen in my Mensuration, pa. 190, 4th edit.

IDE'S, in the Roman Calendar, a name given to a series of 8 days in each month; which, in the full months, March, May, July, and October, commenced on the 15th day; and in the other months, on the 13th day; from thence reckoned backward, so as in those four months to terminate on the 8th day, and in the rest on the 6th. These came between the calends and the nones. And this way of counting is still used in the Roman Chancery, and also in the Calendar of the Breviary.

JET D'EAU, a French word, signifying a fountain that throws up water to some height in the air. A jet of water is thrown up by the weight of the column of water above its ajutage, or orifice, up to its source or reservoir; and therefore it would rise to the same height precisely as the head or reservoir, if certain causes were removed which prevent it from rising quite so high. For first, the velocity of the lower particles of the jet being greater than that of the upper, the lower water strikes that which is next above it; and as fluids press every way, by its impulse it widens, and consequently shortens the column. Secondly, the water at the top of the jet does not immediately fall off, but forms a kind of ball or head, the weight of which depresses the jet; but if the jet be little inclined, or not quite upright, it will play higher, though it will not in such case be quite so beautiful. Thirdly, the friction against the sides of the pipe and hole of the ajutage, prevents the jet from rising quite so high, and a small one will be more impeded than a large one. And the fourth cause is the resistance of the air, which is proportional to the square of the velocity of the water nearly; and therefore the defect in the height is nearly in the same proportion, which is also the same as the proportion of the heights of the reservoirs above the ajutage. Hence, and from experience, it is found that a jet, properly constructed, rises to different heights according to the height of the reservoir, as in the following table, Of the heights of reservoirs and the heights of their corresponding jets; the former in feet, and the latter in feet, and tenths of a foot.

Heights of Reservoirs and their Jets.

By various experiments that have been made by Mariotte, Desaguliers, and others, it has been found, that if the reservoir be 5 feet high, a conduct-pipe $1\frac{1}{2}$ inch diameter will admit a hole in the ajutage from $\frac{1}{4}$ to $\frac{3}{8}$ of an inch; and so on as in the following table:

Height Reservoir.	Diam. of the Ajutage.	Diam. of the Conduct-Pipe.
5 feet	- $\frac{1}{4}$ to $\frac{3}{8}$ inch	- $1\frac{1}{4}$ inch
10	- $\frac{1}{4}$ to $\frac{1}{2}$	- 2
15	- $\frac{1}{2}$	- $2\frac{1}{4}$
20	- $\frac{1}{2}$	- $2\frac{1}{2}$
25	- $\frac{1}{2}$	- $2\frac{3}{4}$
30	- $\frac{1}{2}$ to $\frac{3}{4}$	- $3\frac{1}{4}$
40	- $\frac{3}{4}$	- $4\frac{1}{2}$
50	- $\frac{3}{4}$	- $5\frac{1}{4}$
60	- 1	- $5\frac{3}{4}$ or 6
80	- $1\frac{1}{4}$	- $6\frac{1}{2}$ or 7
100	- $1\frac{1}{4}$ to $1\frac{1}{2}$	- 7 or 8

But the size of the pipe is more or less, with the distance.

If it be required to keep any number of jets of given dimensions playing, by one common conduct-pipe, the diameter of an ajutage must be found that shall be equal to all the small ones that are given, and from this its proper conduct-pipe. Thus, if there be 4 ajutages, each $\frac{3}{4}$ of an inch diameter; then the square of $\frac{3}{4}$ is $\frac{9}{16}$, which multiplied by 4, the number of them, makes $\frac{36}{16}$, the square root of which is $\frac{6}{4}$ or $1\frac{1}{2}$, the diameter of an ajutage equal to all the other four; to which in the table answers a pipe of 8 inches diameter. In general, the diameter of the conduct-pipe should be about 6 times that of the ajutage.—See Mariotte's *Mouvement des Eaux*; Desaguliers's *Exper. Philos.* vol. 2, pa. 127, &c.; Clare's *Motion of Fluids*, pa. 109; &c.

JETTE, the border made round the stilts under a pier, in certain old bridges, being the same with starling, consisting of a strong framing of timber filled with stones, chalk, &c.; to preserve the foundations of the piers from injury.

IGNIS FATUUS, a common meteor, chiefly seen in dark nights about meadows, marshes, and other moist places, as also in burying-grounds, and near dung-hills. It is known among the people by the appellations, Will with a Wisp, and Jack with a Lantern. Dr. Shaw describes a remarkable ignis fatuus, which he saw in the Holy Land,

that was sometimes globular, or in the form of the flame of a candle; and presently afterwards it spread itself so much as to involve the whole company in a pale insinuous light, and then contract itself again, and suddenly disappear. But in less than a minute it would become visible as before; or, running along from one place to another, with a swift progressive motion, would expand itself at certain intervals over more than 2 or 3 acres of the adjacent mountains. The atmosphere had been thick and hazy, and the dew on the horses' bridles was uncommonly clammy and unctuous. In the same weather he observed those luminous appearances, which skip about the masts and yards of ships at sea, and which the sailors call corpusane, by a corruption of the Spanish *cuerposanto*. Shaw's Travels, pa. 363.

Newton calls it a vapour shining without heat; and supposed it to be of the same nature with the light issuing from putrescent substances. Willooughby and Ray were of opinion that it is occasioned by shining insects: but all the appearances of it observed by Derham, Beccaria, and others, sufficiently evince that it must be an ignited vapour. Inflammable air has been found to be the most common of all the factitious airs in nature; and that it is the usual product of the putrefaction and decomposition of vegetable substances in water. Signor Volta writes to Dr. Priestley, that he fires inflammable air by the electric spark, even when the electricity is very moderate; and he supposes that this experiment explains the inflammation of the ignis fatuus, provided they consist of inflammable air, issuing from marshy ground by help of the electricity of fogs, and by falling stars, which have probably an electrical origin. See Priestley's Obs. on Air, vol. 3, pa. 382; the Philos. Trans. Abr. vol. 7, pa. 374, &c.

IGNITION, properly signifies the setting fire to any substance; but the sense is commonly restrained to that kind of burning which is not accompanied with flame, such as of charcoal, cinders, metals, stones, and other solid substances. The effects of ignition are first to dissipate what is called the phlogiston of the ignited body, after which it is reduced to ashes. Vitrification next follows; and lastly, the substance is totally dissipated in vapour. All these effects, however, depend on the presence of the air; for in *vacuo* the phlogiston of any substance cannot be dissipated. Neither can a body which is totally destitute of phlogiston be ignited in such a manner as those which contain it; for as long as the phlogiston remains, the heat is kept up in the body by the action of the external air upon it: but when the phlogiston is entirely evaporated, the air always destroys, instead of augmenting the heat. Philosophers have therefore been greatly embarrassed in explaining the phenomena of ignition. See PHLOGISTON.

ILLUMINATION, the act or effect of a luminous body, or a body that emits light; sometimes also the state of another body that receives it.

Circle of ILLUMINATION. See CIRCLE.

ILLUMINATIVE Lunar Month, the space of time that the moon is visible, between one conjunction and another.

IMAGE, in Optics, is the spectre or appearance of an object, made either by reflection or refraction. In all plane mirrors, the image is of the same magnitude as the object; and it appears as far behind the mirror as the object is before it. In convex mirrors, the image appears less than the object; and farther distant from the centre of the convexity, than from the point of reflection. Mr.

Molyneux gives the following rule for finding the diameter of an image, projected in the distinct base of a convex mirror: viz, As the distance of the object from the mirror is to the distance of the image from the glass, so is the diameter of the object to the diameter of the image. See LENS, MIRROR, REFLECTION, and REFRACTION.

IMAGINARY Quantities, or Impossible Quantities, in Algebra, are the even roots of negative quantities; which expressions are imaginary, or impossible, or opposed to real quantities; as $\sqrt{-aa}$, or $\sqrt{-a^4}$, &c. For, as every even power of any quantity whatever, whether positive or negative, is necessarily positive, or having the sign +, because + by +, or - by - give equally +; hence it follows that every even power, as the square for instance, which is negative, or having the sign -, has no possible root; and therefore the even roots of such powers or quantities are said to be impossible, or imaginary. The mixt expressions arising from imaginary quantities joined to real ones, are also imaginary; as $a - \sqrt{-aa}$, or $b + \sqrt{-aa}$.

The roots of negative quantities were, perhaps, first treated of in Cardan's Algebra. As to the uneven roots of such quantities, he shows that they are negative, and at the same time assigns them: but the even roots of them he rejects, observing that they are nothing as to common use, being neither one thing or other; that is, they are merely imaginary or impossible. And since his time, it has gradually become a part of algebra to treat of the roots of negative quantities. Albert Girard, in his Invention Nouvelle en l'Algebre, pa. 42, gives names to the three kinds of roots of equations, calling them, greater than nothing, less than nothing, and envelopée, as $\sqrt{-3}$: but this was soon after called imaginary or impossible, as appears by Wallis's Algebra, pa. 264 &c; where he observes that the square root of a negative quantity, is a mean proportional between a positive and a negative quantity; as $\sqrt{-bc}$ is the mean proportional between $+b$ and $-c$, or between $-b$ and $+c$; and this he exemplifies by geometrical constructions. See also pa. 313.

The arithmetic of these imaginary quantities has not yet been generally agreed on; viz, as to the operations of multiplication, division, and involution; some authors giving the results with +, and others on the contrary with the negative sign -. Thus, Euler, in his Algebra, pa. 106 &c, makes the square of $\sqrt{-3}$ to be -3 , of $\sqrt{-1}$ to be -1 , &c; and yet he makes the product of two impossibles, when they are unequal, to be possible and real: as $\sqrt{-2} \times \sqrt{-3} = \sqrt{6}$; and $\sqrt{-1} \times \sqrt{-4} = \sqrt{4}$ or 2. But how can the equality or inequality of the factors cause any difference in the signs of the products? If $\sqrt{-2} \times \sqrt{-3}$ be $= \sqrt{+6}$, how can $\sqrt{-3} \times \sqrt{-2}$, which is the square of $\sqrt{-3}$, be -3 ? Again, he makes $\sqrt{-3} \times \sqrt{+5} = \sqrt{-15}$. Also in division, he makes $\sqrt{-4} \div \sqrt{-1}$ to be $= \sqrt{+4}$ or 2; and $\sqrt{+3} \div \sqrt{-3} = \sqrt{-1}$; also that $1 \text{ or } \sqrt{+1} \div \sqrt{-1} = \sqrt{\frac{+1}{-1}} = \sqrt{-1}$; consequently, multiplying the quotient root $\sqrt{-1}$ by the divisor $\sqrt{-1}$, must give the dividend $\sqrt{+1}$; and yet, by squaring, he makes the square of $\sqrt{-1}$, or the product $\sqrt{-1} \times \sqrt{-1}$, equal to -1 .

But Emerson makes the product of imaginaries to be imaginary; and for this reason, that "otherwise a real product would be raised from impossible factors, which is absurd. Thus, $\sqrt{-a} \times \sqrt{-b} = \sqrt{-ab}$, and $\sqrt{-a} \times -\sqrt{-b} = -\sqrt{-ab}$, &c. Also $\sqrt{-a} \times \sqrt{-a} = -a$, and $\sqrt{-a} \times -\sqrt{-a} = +a$, &c." And thus

most of the writers on this part of algebra are pretty equally divided, some making the product of impossible real, and others imaginary.—In the Phil. Trans. for 1778, pa. 318 &c, Mr. Playfair has given an ingenious dissertation on the Arithmetic of Impossible Quantities. But this relates chiefly to their applications and uses, and not to the algorithm of them, or rules for their products, quotients, squares, &c. From some operations however here performed, we learn that he makes the product of $\sqrt{-1}$ by $\sqrt{-1}$, or the square of $\sqrt{-1}$, to be -1 ; and yet in another place he makes the product of $\sqrt{-1}$ and $\sqrt{(1-z)}$ to be $\sqrt{(-1+z)}$. This author concludes, "that imaginary expressions are never of use in investigations but when the subject is a property common to the measures both of ratios and of angles; that they never lead to any consequence which might not be drawn from the affinity between those measures; and that they are indeed no more than a particular method of tracing that affinity. The deductions into which they enter are thus reduced to an argument from analogy, but the force of them is not diminished on that account. The laws to which this analogy is subject; the cases in which it is perfect, in which it suffers certain alterations, and in which it is wholly interrupted, are capable of being precisely ascertained. Supported on so sure a foundation, the arithmetic of impossible quantities will always remain an useful instrument in the discovery of truth, and may be of service when a more rigid analysis can hardly be applied. For this reason, many researches concerning it, which themselves might be deemed absurd, are nevertheless not destitute of utility. M. Bernoulli has found, for example, that if r be the radius of a circle, the circumference is $= \frac{4 \log \sqrt{-1}}{\sqrt{-1}} r$. Considered as a quadrature of the circle, this imaginary theorem is wholly insignificant, and would deservedly pass for an abuse of calculation; at the same time we learn from it, that if in any equation the quantity $\frac{\log \sqrt{-1}}{\sqrt{-1}}$ should occur, it may be made to disappear, by the substitution of a circular arch, and a property, common to both the circle and hyperbola, may be obtained. The same is to be observed of the rules which have been invented for the transformation and reduction of impossible quantities"; they facilitate the operations of this imaginary arithmetic, and thereby lead to the knowledge of the most beautiful and extensive analogy which the doctrine of quantity has yet exhibited.

* The rules chiefly referred to, are those for reducing the impossible roots of an equation to the form $a + b\sqrt{-1}$.

IMAGINARY Roots, of an equation, are those roots or values of the unknown quantity in an equation, which contain some imaginary quantity. So the roots of the equation $xx + aa = 0$, are the two imaginary quantities $+\sqrt{-aa}$ and $-\sqrt{-aa}$, or $+a\sqrt{-1}$ and $-a\sqrt{-1}$; also the two roots of the equation $xx + ax + aa = 0$, are the imaginary quantities $+\frac{1}{2}a - \frac{1}{2}a\sqrt{-3}$; and the three roots of the equation $x^2 - 1 = 0$, or $x^2 = 1$, are $1, -\frac{1+\sqrt{-3}}{2}$, and $\frac{-1-\sqrt{-3}}{2}$; the first real, and the

two latter imaginary. Sometimes the real root of an equation may be expressed by imaginary quantities; as in the irreducible case of cubic equations, when the root is expressed by Cardan's rule; and that happens whenever the equation has no imaginary roots at all; but when it has two imaginary roots, then the only real root is ex-

pressed by that rule in an imaginary form. See my paper on Cubic Equations, in my Tracts, vol. 2, pa. 78. Philos. Trans. for 1780, pa. 406 &c.

Albert Girard first treated expressly on the impossible of imaginary roots of equations, and stated that every equation has as many roots, either real or imaginary, as the index of the highest power denotes. Thus, the roots of the biquadratic equation $x^4 = 4x - 3$, are four, which he shows to be two real and two imaginary, viz. 1, 1, $-1 + \sqrt{-2}$, and $-1 - \sqrt{-2}$; and he renders the relation general, between all the roots and the coefficients of the terms of the equation. See his Invention Nouvelle en l'Algèbre, anno 1629, theor. 2, pa. 40 &c.

M. Dalembert demonstrated, that every imaginary root of any equation can always be reduced to the form $e + f\sqrt{-1}$, where e and f are real quantities. And hence it was also shown, that if one root of an equation be $-e + f\sqrt{-1}$, another root of it will always be $-e - f\sqrt{-1}$: and hence it appears that the number of the imaginary roots in any equation is always even, if any; i. e. either none, or else two, or four, or six, &c. Memoirs of the Academy of Berlin, 1746.

To discover how many impossible roots are contained in any proposed equation, Newton gave this rule, in his Algebra, viz. Constitute a series of fractions, whose denominators are the series of natural numbers 1, 2, 3, 4, 5, &c, continued to the number showing the index or exponent of the highest term of the equations, and their numerators the same series of numbers in the contrary order: and divide each of these fractions by that next before it, and place the resulting quotients over the immediate terms of the equation; then under each of the intermediate terms, if its square multiplied by the fraction over it, be greater than the product of the terms on each side of it, place the sign +; but if not, the sign -; and under the first and last term place the sign +. Then will the equation commonly have as many imaginary roots as there are changes of the underwritten signs, from + to -, and from - to +. So for the equation $x^3 - 4x^2 + 4x - 6 = 0$, the series of fractions is $\frac{1}{1}, \frac{2}{2}, \frac{3}{1}$; then the second divided by the first gives $\frac{2}{1}$ or $\frac{3}{2}$, and the third divided by the second gives $\frac{3}{2}$ also; hence these quotients placed over the intermediate terms, the whole will stand

$$\text{thus, } x^3 - 4x^2 + 4x - 6.$$

$$\begin{array}{cccc} \frac{1}{1} & \frac{2}{2} \\ + & + & - & + \end{array}$$

Now because the square of the 2d term multiplied by its superscribed fraction, is $\frac{1}{1}x^4$, which is greater than $4x^2$ the product of the two adjacent terms, therefore the sign + is set below the 2d term; and because the square of the 3d term multiplied by its overwritten fraction, is $\frac{1}{2}x^2$, which is less than $24x^2$ the product of the terms on each side of it, therefore the sign - is placed under that term; also the sign + is set under the first and last terms. Hence the two changes of the underwritten signs + + - +, the one from + to -, and the other from - to +, show that the given equation has two impossible roots. When two or more terms are wanting together, under the place of the 1st of the deficient terms write the sign -, under the 2d the sign +, under the 3d -, and so on, always varying the signs, except that under the last of the deficient terms must always be set the sign +, when the adjacent terms on both sides of the deficient terms have contrary signs. As in the equation

$$x^5 + a^4x^2 \times \times \times + a^5 = 0,$$

$$\begin{array}{cccccc} + & + & - & + & - & + \end{array}$$

which has four imaginary roots; there being four changes in the signs as written. The author remarks, that this rule will sometimes fail of discovering all the impossible roots of an equation, for some equations may have more of such roots than can be found by this rule, though this seldom happens.

Mr. Maclaurin has given some account of this rule of Newton's, together with one of his own, which he says will never fail; and the same has also been done by Mr. Campbell; but none of them obtain universally. See Philos. Trans. vol. 34, pa. 104, and vol. 35, pa. 515. More accurate rules have been since given by Dr. Waring.

The real and imaginary roots of equations may be found from the method of fluxions, applied to the doctrine of maxima and minima, that is, to find such a value of x in an equation, expressing the nature of a curve, made equal to y , an abscissa which corresponds to the greatest and least ordinate. But when the equation is above 3 dimensions, the computation is very laborious. See Stirling's treatise on the lines of the 3d order, Schol. pr. 8, pa. 59 &c.

IMBIBE, is commonly used in the same sense as absorb, viz, where a dry porous body takes up another that is moist.

IMMENSE, that whose amplitude or extension cannot be equalled by any measure whatever, or how often soever repeated.

IMMERSION, the act of plunging into water, or some other fluid.

IMMERSION, in Astronomy, is when a star, or planet comes so near the sun, that it cannot be seen; being as it were enveloped, and hid in the rays of that luminary.

IMMERSION also denotes the beginning of an eclipse, or of an occultation, when the body, or any part of it just begins to disappear, either behind the edge of another body, or in its shadow. As, in an eclipse of the moon, when she begins to be darkened by entering into the shadow of the earth: or the beginning of an eclipse of the sun, when the moon's disc just begins to cover him: or the beginning of the eclipses of any of the satellites, as those of Jupiter, by entering into his shadow: or, lastly, the beginning of an occultation of any star or planet, by passing behind the body of the moon or another planet. In all these cases, the darkened body is said to immerse, or to be immerged, or begin to be hid, by entering into the shade. In like manner, when the darkened body begins to appear again, it is said to emerge, or come out of darkness again.

IMPACT, the simple or single action of one body upon another to put it in motion. Point of impact, is the place or point where a body acts.—Impact is either direct or oblique: if the body struck moves in the direction of the stroke, the impact is said to be direct; but if not, it is called an oblique impact.

IMPENETRABILITY, the faculty which a body has to exclude every other body from the place that it occupies: in such manner that two bodies, placed in contact, can never occupy less space than that which they filled when they were separate.

Impenetrability, as it respects solid bodies, does not require to be proved, it is at once obvious; but fluids having their molecule moveable in all directions, and yielding to every impression exerted on them, their impenetrability does not manifest itself so perceptibly as that

of solid bodies. Taking the air for an example: it is evident that so long as this fluid is not enclosed, its facility of motion causes it to admit an easy and free passage to all bodies that are urged through it; and in this case, it cannot be said to be penetrated, but displaced; for, if the air be included within the sides of a vessel, and another body be then presented to take its place, without suffering it to escape, it will exercise its impenetrability in the same manner as solid bodies. This may be sufficiently evinced by the following very easy and simple experiment: Let a vessel be vertically detrued into another vessel filled with water to a certain height, with its orifice downwards: the surface of the water corresponding with the orifice of the first vessel, is depressed as this vessel itself descends; and this depression may be rendered more sensible by means of a little plate or slip of cork, placed so as to float on the surface of the water: nevertheless, this water is not excluded by the air which occupies the immersed vessel; it is always raised within it by a certain quantity which increases as the vessel is immersed to a greater depth, similar to what is observed in the diving-bell; but it is evident that this ascension of the fluid is occasioned by the circumstance that the air is a compressible fluid, and not from any penetration of the water into the bulk of air in the vessel; and therefore its volume is only contracted into a smaller space by a superior upward pressure of the surrounding water in virtue of its weight.

We must here notice a difficulty which appears to result from this, that when certain bodies are mingled together, the volume of the mixture is less than the sum of the volumes taken separately. This happens, for example, in the mixture of equal parts of alcohol and water; the same also obtains when copper by fusion is mingled with zinc, in order to form the compound metal called brass: it is then observed that the density of the mixture is augmented by about its tenth part. This apparent penetration is owing to the circumstance, that the molecule of the two bodies, in consequence of their respective formation, have a stronger attraction than in the two bodies taken separately; there hence results in the figure of the pores such a change as diminishes the space equal to the sum of these pores. On the contrary, in the alloy of silver with copper, a kind of rarefaction is produced, such that the volume of the mixture is somewhat greater than the sum of the capacities of the two bodies previous to fusion.

IMPERENTRABLE, that cannot be penetrated.

IMPERFECT Number, is that whose aliquot parts, taken all together, do not make a sum that is equal to the number itself, but either exceed it, or fall short of it; being an abundant number in the former case, and a defective number in the latter. Thus, 12 is an abundant imperfect number, because the sum of all its aliquot parts, 1, 2, 3, 4, 6, is 16, which exceeds the number 12. And 10 is a defective imperfect number, because its aliquot parts, 1, 2, 5, taken all together, make only 8, which is less than the number 10 itself.

IMPERIAL Table, is an instrument made of brass, with a box and needle, and staff, &c, used for measuring of land.

IMPERVIOUS, not to be pervaded or entered either because of the closeness of the pores, or the particular configuration of its parts.

IMPETUS, in Mechanics, force, momentum, motion, &c.

IMPETUS, in Gunnery, is the altitude due to the first force of projection, or the altitude through which a body by falling acquires that velocity. So that, if the velocity be v , the impetus or altitude will be $a = v^2 \div 64\frac{1}{2}$ feet.

IMPOSSIBLE Quantity, or Root, the same as

IMAGINARY ones; which see.

IMPOSSIBLE Binomial; see BINOMIAL.

IMPOST, in Architecture, a capital or plinth, to a pillar, or pilaster, or pier, that supports an arch, &c.

IMPROPER Fraction, is a fraction whose numerator is either equal to, or greater than, its denominator. As $\frac{5}{3}$ or $\frac{5}{2}$ or $\frac{19}{8}$. An improper fraction is reduced to a whole or mixt number, by dividing the numerator by the denominator; the quotient is the integer, and the remainder set over the divisor makes the fractional part, of the value of the original improper fraction. Thus $\frac{5}{3} = 1$, and $\frac{5}{3} = 1\frac{2}{3}$, and $\frac{19}{8} = 2\frac{3}{8}$. So that, when the numerator is just equal to the denominator, the improper fraction is exactly equal to unity or 1; but when the numerator is the greater, the fraction is greater than 1.

IMPULSE, the single or momentary action or force by which a body is impelled; in contradistinction to continued forces; like the blow of a hammer.

IMPULSIVE, a term applied to actions by impulse.

INACCESSIBLE Height or Distance, is that which cannot be approached, or measured by actual measurement, by reason of some impediment; as water, &c.—See HEIGHTS and DISTANCES.

INCEPTIVE, of *Magnitude*, a term used by Dr. Wallis, to express such moments, or first principles, as, though of no magnitude themselves, are yet capable of producing such as are. See INFINITE, and INDIVISIBLE. Thus, a point has no magnitude, but is inceptive of a line, which it produces by its motion. Also a line, though it has not breadth, is yet inceptive of breadth; that is, it is capable, by its motion, of producing a surface, which has breadth.

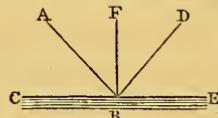

INCH, a common English measure, being the 12th part of a foot, or 3 barley-eorns in length.

INCIDENCE, or Line of Incidence, in Mechanics, implies the direction or inclination in which one body strikes or acts on another.—In the incursions of two moving bodies, their incidence is said to be direct or oblique, as the directions of their motion make a straight line, or an angle at the point of impact.

Angle of Incidence, by some writers, denotes the angle comprehended between the line of incidence, and a perpendicular to the body acted on at the point of incidence. Thus, suppose AB an incident line, and BF a perpendicular to the plane CB at the incident point B ; then ABF is the angle of incidence, or of inclination.

But, according to Dr. Barrow, and some other writers, the angle of incidence is the complement of the former, or the angle made between the incident line, and the plane acted on, or a tangent at the point of incidence: as the angle ABC .

It is demonstrated by optical writers, 1st, That the angle of incidence of the rays of light, is always equal to the angle of reflection; and that they lie in the same plane. And the same is proved by the writers on mechanics, concerning the reflection of elastic bodies. That is, the $\angle ABF = \angle FBD$, or the $\angle ABC = \angle DBE$.—

2d, That the sines of the angles of incidence and refraction are to each other, either accurately, or very nearly, in a given or constant ratio.—**3dly**, That from air into glass, the sine of the angle of incidence is to the sine of the angle of refraction, as 300 to 193, or nearly as 14 to 9: and, on the other hand, that out of glass into air, the sine of the angle of incidence, is to the sine of the angle of refraction, as 193 to 300, or as 9 to 14 nearly.

INCIDENCE of Eclipse. See ECLIPSE, and IMMERSION.

Axis of Incidence, is the line FB perpendicular to the reflecting plane at the point of incidence B .

Cathetus of Incidence. See CATHETUS, and REFLECTION.

Line of Incidence, in Catoptrics, denotes a right line, as AB , in which light is propagated from a radiant point A , to a point B , in the surface of a speculum. The same line is also called an incident ray.

Line of Incidence, in Dioptrics, is a right line, as AB , in which light is propagated unrefracted, in the same medium, from the radiant point to the surface of the refracting body, CBE .

Point of Incidence, is the point B on the surface of the reflecting or refracting medium, on which the incident ray falls.

Scruples of Incidence. See SCRUPLES.

INCIDENT Ray, is the line or ray AB , falling on the surface of any body, at B .

INCLINATION, in Geometry, Mechanics, or Physics, denotes the mutual tendency of two lines, planes, or bodies, towards each other; so that their directions make at the point of concourse some certain angle.

INCLINATION of the Axis of the Earth, is the angle it makes with the plane of the ecliptic; or the angle between the planes of the equator and ecliptic.

INCLINATION of a Line to a Plane, is the acute angle, as CDE , which the line CD makes with another line DE drawn in the plane through the incident point D and the foot of a perpendicular E , from any point of the line, upon the plane.

INCLINATION of an Incident Ray, is the angle of inclination, or angle of incidence.

INCLINATION of the Magnetical Needle. See DIPPING NEEDLE.

INCLINATION of Meridians, in Dialling, is the angle that the hour-line on the globe, which is perpendicular to the dial-plane, makes with the meridian.

INCLINATION of the Orbit of a Planet, is the angle formed by the planes of the ecliptic and of the orbit of the planet. The quantity of this inclination for the several planets, is as follows, viz.

Mercury	-	-	6° 54'	0"
Venus	-	-	3 23	35
Earth	-	-	0 0	0
Moon	-	-	5 18	0
Mars	-	-	1 51	0
Jupiter	-	-	1 18	56
Saturn	-	-	2 29	50
Herschel	-	-	0 46	20

INCLINATION of a Plane, in Dialling, is the arch of a vertical circle, perpendicular both to the plane and the horizon, and intercepted between them.

INCLINATION of a Planet, is the arch or angle com-

prehended between the ecliptic and the place of the planet in its orbit. The greatest inclination, or declination, is the same as the inclination of the orbit; which see above.

INCLINATION of a Reflected Ray, is the angle which a ray after reflection makes with the axis of inclination; as the angle FBD , in the last fig. but one.

INCLINATION of Two Planes, is the angle made by two lines drawn in those planes perpendicular to their common intersection, and meeting in any point of that intersection.

Angle of Inclination, is the same as what is otherwise called the angle of incidence.

Argument of Inclination. See ARGUMENT.

INCLINATIONS (Problem of), is one of the last works of Apollonius, described by Pappus, as consisting of two books. Of these, restorations have been attempted by several of the moderns, with various success. 1st, By Ghealdus, in two books entitled Apollonius Redivivus, 4to, Venice, 1607 & 1613.—2d, Alex. Anderson, Suppl. Apol. Rediv. Inclin. Paris, 1612, & 1615, 4to.—3d, Horsley, Apol. Inclin. lib. 2, Oxon, 1770, 4to.—4th, Reuben Burrow published an English edition in 1779, 4to.

INCLINED Plane, in Mechanics, is a plane inclined to the horizon, or making an angle with it. It is one of the simple mechanic powers, and the double inclined plane makes the wedge.

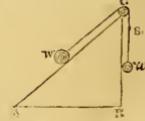

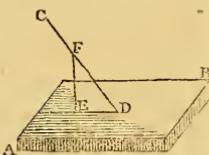

1. The power gained by the inclined plane, is in proportion as the length of the plane is to its height, or as radius to the sine of its inclination; that is, a given weight hanging freely, will balance upon the plane another weight, that shall be greater in that proportion. So, when the greater weight w on the plane, is balanced by the less weight w , hanging perpendicularly, then is $w : w :: BC : AC :: \sin. \angle A : \text{radius}$. Or, in other words, the relative gravity of a body upon the plane, or its force in descending down the plane, is to its absolute gravity or weight, in the same proportion of the height of the plane to its length, or of the sine of inclination to radius.

2. Hence therefore the relative gravities of the same body on different inclined planes, or their forces, to descend down the planes, are to each other, as the sines of the angles of inclination, to radius 1, or directly as the heights of the planes, and inversely as their lengths.

3. Hence, if the planes have the same height, and the absolute weights of the bodies be directly proportional to the lengths of the planes, then the forces to descend will be equal. Consequently, if the bodies be then connected by a string acting parallel to the planes, they will exactly balance each other; as in the annexed figure.

4. The relative force of gravity on the plane being in a constant ratio to the absolute weight of the body, viz, as sine of inclination to radius; therefore all the laws relating to the perpendicular free descents of bodies by gravity, hold equally true for the descents on inclined planes; such as, that the motion is a uniformly accelerated one; that the velocities are directly as the times, and the spaces as the square of either of them; using only the relative force upon the plane for the absolute weight of the body, or instead of $32\frac{1}{6}$ feet, the velocity generated by gravity in the first second of time, using $32\frac{1}{6}s$, where s is the sine of the inclination to the radius 1.

5. The velocity acquired by a body in descending

down an inclined plane AC , when the body arrives at A , is the same as the velocity acquired by descending freely down the perpendicular altitude BC , when it arrives at B . But the times are very different; for the time of descending down the inclined plane, is greater than down the perpendicular, in the same proportion as the length of the plane AC , is to the height CB : and so the time of descending from any point C to a horizontal line or plane ABG &c, down any oblique line, or inclined plane, is directly proportional to the length of that plane, CA , or CD , or CE , or CB , or CF , &c.

6. Hence, if there be drawn AH perpendicular to AC , meeting CB produced in H ; then the time of descending down any plane CA , is equal to the time of descending down the perpendicular CH . So that, if upon CH , as a diameter, a circle be described, the times of descent will be exactly equal, down every chord in the circle, beginning at C , and terminating any where in the circumference, as CI , CA , CK , CH , &c, or beginning any where in the circumference, and ending at the lowest point of the circle, as CH , IH , AH , KH , &c.

7. When bodies ascend inclined planes, their motion is uniformly retarded; and all the former laws for descents, or the generation of motion, hold equally true for ascents, or the destruction of the same.

INCLINED Towers, are towers inclined, or leaning from the perpendicular, as those of Pisa or Bologna in Italy. See **Towers**.

INCLINERS, are inclined dials. See **DIAL**.

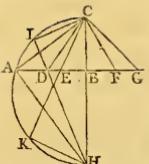

INCOMMENSURABLE, Lines, or Numbers, or Quantities in general, are such as have no common measure, or no line, number, or quantity of the same kind, that will measure or divide them both without a remainder. Thus, the numbers 15 and 16 are incommensurable, because, though 15 can be measured by 3 and 5, and 16 by 2, 4, and 8, there is yet no single number that will divide or measure them both.—Euclid demonstrates (prop. 117, lib. 10) that the side of a square and its diagonal are incommensurable to each other. And Pappus, prop. 17, lib. 4, speaks of incommensurable angles.

INCOMMENSURABLE in Power, is said of quantities whose 2d powers, or squares, are incommensurable. As $\sqrt{2}$ and $\sqrt{3}$, whose squares are 2 and 3, which are incommensurable. It is commonly supposed that the diameter and circumference of a circle are incommensurable to each other; at least their commensurability has never been proved. And Dr. Barrow surmises even that they are infinitely incommensurable, or that all possible powers of them are incommensurable.

INCOMPOSITE Numbers, are the same with those called by Euclid prime numbers, being such as are not composed by the multiplication together of other numbers. As 3, 5, 7, 11, &c.

INCOMPRESSIBLE, incapable of being squeezed into less room.

INCOMPRESSIBILITY, incapacity to be compressed into less room.—During a long period, water was considered as a fluid perfectly inelastic, that is, incompressible or unyielding; and this opinion was corroborated by an experiment of the Academy del Cimento in Italy. By that experiment, the members of the academy endeavoured to ascertain whether water was capable of being com-

pressed in any degree. For this purpose, they filled a hollow metallic globe with that fluid, and closed the orifice very accurately. This ball was then forcibly pressed in a proper machine; but no contraction could be observed, neither indeed was the apparatus capable of showing small degrees of compression: hence however they concluded that water was not capable of compression. This opinion prevailed till the year 1761, when Mr. Canton discovered the compressibility of water, and of other liquids. He took a glass tube, having a hollow ball at one end, but open at top; he filled the ball and part of the tube with water, which he had deprived of air as much as possible; he then placed the glass thus filled under the receiver of an air-pump; and on exhausting the receiver, which removed the pressure of the atmosphere from over the water and the glass vessel, the consequence was, that the water rose a little way in the tube, that is, it expanded itself. He then placed the apparatus under the receiver of a condensing engine, and on forcing the air into it, which increased the pressure on the water, a diminution of bulk visibly took place, the water descending a little in the tube. “In this manner,” says Mr. Canton, “I have found by repeated trials, when the heat of the air has been about 50° , and the mercury at a mean height in the barometer, that the water will expand and rise in the tube, by removing the weight of the atmosphere, one part in 21740, and will be as much compressed under the weight of an additional atmosphere. Therefore the compression of water by twice the weight of the atmosphere, is one part in 10870. Water has also the remarkable property of being more compressible in winter than in summer, which is contrary to what I have observed both in spirits of wine and oil of olives.” By the same means, and in the same circumstances, Mr. Canton ascertained compressibility in some other fluids, the results of which are as below: viz,

	<i>Compression of</i>	<i>Millionth parts.</i>
Spirit of wine	-	66
Oil of olives	-	48
Rain-water	-	46
Sea-water	-	40
Mercury	-	3

INCREMENT, is the small increase of a variable quantity. Newton, in his Treatise on Fluxions, calls these by the name Moments, and observes that they are proportional to the velocity or rate of increase of the flowing or variable quantities, in an indefinitely small time; he denotes them by subjoining a cipher 0, to the varying quantity whose moment or increment it is; thus $x0$ is the moment of x . In the doctrine of increments, by Dr. Brooke Taylor and Mr. Emerson, they are denoted by points below the variable quantities; as \bar{x} . Some have also represented them by accents underneath the letter, as \bar{x} ; but it is now more usual to express them by accents over the same letter; as \bar{x}' .

INCREMENTS, *Method of*, a branch of Analytics, in which a calculus is founded on the properties of the successive values of variable quantities, and their differences, on increments. The inventor of this method was the learned Dr. Taylor, who, in the year 1715, published a treatise upon it; and afterwards gave some further account and explication of it in the Philos. Trans. as applied to the finding the sums of series. Another ingenious and easy treatise on the same, was published by Mr. Emerson, in the year 1763. The method is nearly allied to New-

ton's doctrine of fluxions, and arises out of it. Also the differential method of Mr. Stirling, which he applies to the summation and interpolation of series, is of the same nature as the method of increments, but not so general and extensive.

From the method of increments, Mr. Emerson observes, "the principal foundation of the method of fluxions may be easily derived. For, as in the method of increments, the increment may be of any magnitude, so in the method of fluxions, it must be supposed infinitely small; whence all preceding and successive values of the variable quantity will be equal, from which equality the rules for performing the principal operations of fluxions are immediately deduced. That I may give the reader," continues he, "a more perfect idea of the nature of this method: suppose the abscissa of a curve to be divided into any number of equal parts, each part of which is called the increment of the abscissa; and imagine so many parallelograms to be erected thereon; either circumscribing the curvilinear figure, or inscribed in it; then the finding the sum of all these parallelograms belongs to the method of increments. But if the parts of the abscissa be taken infinitely small, then these parallelograms degenerate into the curve; and then it becomes the method of fluxions, to find the sum of all, or the area of the curve. So that the method of increments finds the sum of any number of finite quantities; and the method of fluxions the sum of any infinite number of infinitely small ones: and this is the essential difference between these two methods." Again, "There is such a near relation between the method of fluxions, and that of increments, that many of the rules for the one, with little variation, serve also for the other. And here, as in the method of fluxions, some questions may be solved, and the integrals found, in finite terms; while in others we are forced to have recourse to infinite series for a solution. And the like difficulties will occur in the method of increments, as usually happen in fluxions. For while some fluxionary quantities have no fluents, but what are expressed by series; so also some increments have no integrals, but what infinite series afford; which will often, as in fluxions, diverge and become useless."

By means of the method of increments, many curious and useful problems are easily resolved, which scarcely admit of solution in any other way. As, suppose several series of quantities be given, whose terms are all formed according to some certain law, which is also given; the method of increments will determine a general series, which comprehends all particular cases, and from which all of that kind may be found. The method of increments is also of great use in finding any term of a series proposed; having the law given by which the terms are formed; which will either be expressed in finite quantities, or by an infinite series. Another application of the method of increments, is to find the summation of series, which it will often effect in finite terms. And when the sum of a series cannot be had in finite terms, we must have recourse to infinite series; for the integral being expressed by such a series, the sum of a competent number of its terms will give the sum of the series required. This is equivalent to transforming one series into another, converging quicker: and sometimes a very few terms of this series will give the sum of the series sought.

Definitions in the Method of Increments.

- When a quantity is considered as increasing, or decreasing, by certain steps or degrees, it is called an In-

tegral.—2. The increase of any quantity from its present value, to the next succeeding value, is called an increment: or, if it decreases, a decrement.—3. The increase of any increment, is the second increment; and the increase of the 2d increment, is the 3d increment; and so on.

—4. Successing values, are the several values of the integral, succeeding each other in regular order, from the present value; and preceding values, are such as arise before the present value. All these are called by the general term Factors.—5. A perfect quantity is such as contains any number of successive values without intermission; and a defective quantity, is that which wants some of the successive values. Thus $x \ x \ x$ is a perfect quantity; and $x \ x \ x$, an imperfect or defective one.

Notation. This, according to Mr. Emerson's method, is as follows; 1. Simple integral quantities are denoted by any letters whatever, as z , y , x , u , &c.—2. The several values of a simple integral, are denoted by the same letter with small figures under them: so if z be an integral, then z , z , z , z , &c., are the present values, and the 1st, 2d, 3d, &c., successive values of it; and the preceding values are denoted by figures with negative signs, thus z , z , z , z , are the 1st, 2d, 3d, 4th preceding values; and the figure denoting any value, is the characteristic.

3. The increments are denoted with the same letters, and points under them: thus, x is the increment of x , and \bar{x} is the increment of z . Also \bar{x} is the increment of x ; and $\bar{\bar{x}}$ of x , &c.

4. The 2d, 3d, and other increments, are denoted with two, three, or more points: so \bar{z} is the 2d increment of z , and $\bar{\bar{z}}$ is the 3d increment of z , and so on. And these are denominated increments of such an order, according to the number of points.

5. If x be any increment, then $[x]$ is the integral of it; also ${}^2[x]$ denotes the integral of $[x]$, or the 2d integral of x ; and ${}^3[x]$ is the 3d integral of x , or an integral of the 3d order, &c.

6. Quantities written thus,

$x \ . \ . \ . \ x$ mean the same as $x \ x \ x \ x$, or signify that the quantities are continued from the first to the last, without break or interruption.

To find the Increment of any integral, or variable quantity.

Rule 1. If the proposed quantity be not fractional, and be a perfect integral, consisting of the successive values of the variable quantity, which increases uniformly: Multiply the proposed integral by the number of factors, and change the lowest factor for an increment. So the increment of $a - 3x + 6z$ is $-3x + 6z$; for the increment of the constant quantity a is 0 or nothing. So likewise,

The increment of $c \ x \ x \ x \ x$, is $4cx \ x \ x \ x$.

The increment of $ax \ x \ x$, is $3ax \ x \ x$.

The increment of $x \ . \ . \ . \ x$, is $(m + n + 1) \ . \ x \ . \ . \ . \ x$.

Rule 2. In fractional quantities, where the denominator is perfect, and the variable quantity increases uniformly. Multiply the proposed integral by the number of factors, and by the constant increment with a negative sign, and take the next succeeding value into the denominator. Thus,

The increment of $\frac{a}{x \ . \ . \ . \ x}$, is $\frac{-sax}{x \ . \ . \ . \ x}$.

The increment of $\frac{c}{x \dots x^r}$, is $\frac{-9cx}{x \dots x^r}$.

Rule 3. The increment of any power, as x^n is $(x + x)^n - x^n$; that is, the difference between the present value x^n and the next succeeding value $(x + x)^n$. And generally, the increment of any quantity whatever, is found by subtracting the present value, or the given quantity, from its next succeeding value. Also by expanding the compound quantity in a series, and subtracting x^n from it, the increment will be either

$$= nx^{n-1}x + \frac{n(n-1)}{2}x^{n-2}x^2 + \frac{n(n-1)(n-2)}{2 \cdot 3}x^{n-3}x^3 \text{ &c, or}$$

$$= x^n \times : \frac{nx}{x} + \frac{n(n-1)}{2} \frac{x^2}{x^2} + \frac{n(n-1)(n-2)}{2 \cdot 3} \frac{x^3}{x^3} \text{ &c.}$$

So the increment of x^4 , is $(x + x)^4 - x^4 = 4x^3x + 6x^2x^2 + 4x^3x^3 + x^4$

The increment of $\frac{1}{x^3}$ or x^{-3} ,

$$\text{is } \frac{1}{(x+x)^3} - \frac{1}{x^3} = (x+x)^{-3} - x^{-3}$$

$$= -3x^{-4}x + 6x^{-5}x^2 - 10x^{-6}x^3 \text{ &c}$$

$$= -\frac{3x}{x^4} + \frac{6x^2}{x^5} - \frac{10x^3}{x^6} \text{ &c.}$$

The increment of a^x , a being constant, is $a^x - a^x = a^x + x - a^x = a^x \cdot (a^x - 1)$.

The increment of $\frac{1}{a^x}$ is $\frac{1}{a^x} - \frac{1}{a^{x+1}}$

$$= \frac{a^x - a^{x+1}}{a^x a^{x+1}} = \frac{a^x - a^x + x}{a^x a^x + x} = \frac{1 - a^x}{a^x + x}.$$

The increment of xz is $xz - xz =$

$$(x + z) \cdot (z + z) - xz = xz + xz + zz.$$

And so on for any form of integral whatever, subtracting the given quantity from its next succeeding value. So,

The increment of the log. of x is $\log_x - \log_{x+1} x$

$$= \log_x x + x - \log_{x+1} x = \log_x \frac{x+x}{x}, \text{ which, by the nature}$$

of logarithms, is $\frac{x}{x} - \frac{x^2}{2x^2} + \frac{x^3}{3x^3} - \frac{x^4}{4x^4} \text{ &c.}$

Schol. Hence may be deduced the principles and rules of fluxions; for the method of fluxions is only a particular case of the method of increments, fluxions being infinitely small increments; therefore, if in any form of increments, the increment be taken infinitely small, the form or expression will be changed into a fluxional one. Thus, in $xz + xz + zz$, which is the increment of the rectangle xz , if x and z be changed for \dot{x} and \dot{z} , the expression will become $x\dot{z} + \dot{x}z + \dot{x}\dot{z}$ for the fluxion of xz , or only $\dot{x}\dot{z} + \dot{x}\dot{z}$, because $\dot{x}\dot{z}$ is infinitely less than the rest.

So likewise, if \dot{x} be changed for \ddot{x} in this

$$nx^{n-1}x + \frac{n(n-1)}{2}x^{n-2}x^2 + \frac{n(n-1)(n-2)}{2 \cdot 3}x^{n-3}x^3$$

&c, which is the increment of x^n , it becomes

$$nx^{n-1}\dot{x} + \frac{n(n-1)}{2}x^{n-2}\dot{x}^2 + \frac{n(n-1)(n-2)}{2 \cdot 3}x^{n-3}\dot{x}^3$$

&c, or $n^{n-1}\ddot{x}$, for the fluxion of the power x^n , as all the terms after the first will be nothing, because \dot{x}^2 and \dot{x}^3 &c are infinitely less than \dot{x} . And thus may all the other forms of fluxions be derived from the corresponding increments. And in like manner, the finding of the integrals, is only a more general way of finding fluents, as appears in what follows.

Vol. I.

To find the Integral of any given Increment.

Rule 1. When the variable quantity increases uniformly, and the proposed integral consists of the successive values of it multiplied together, or is a perfect increment not fractional: Multiply the given increment by the next preceding value of the variable quantity, then divide by the new number of factors, and by the constant increment.

Example. Thus, the integral of $4xxxx$ is $cxxxx$.

The integral of $3ax x x$ is $ax x x$.

Rule 2. In a fractional expression, where the variable quantity increases uniformly, and the denominator is perfect, containing the successive values of the variable quantity: Expunge the greatest value of the variable letter, then divide by the new number of factors, and by the constant increment with a negative sign. So,

The integral of $\frac{ax}{x \dots x}$ is $\frac{-a}{5x \dots x}$.

The integral of $\frac{-cx}{x \dots x}$ is $\frac{cx}{x \dots x}$.

Rule 3. Various other particular rules are given, but these and the two foregoing are all best included in the following general table of the most useful forms of increments and integrals, to be used in the same way as the similar table of fluxions and fluents, to which these correspond.

A Table of Increments and their Integrals.

Forms.	Increments.	Integrals.
1	x when constant not constant	x , or x , or x , or x &c. x only.
2	$x \dots x$ \dot{x} constant	$x \dots x$ $m + n$
3	$\frac{ax}{x \dots x}$ \dot{x} constant	$-a$ $(m + n - 2) \cdot x \dots x$
4	$xz + xz$	xz
5	$\frac{zz - xz}{z}$	$\frac{x}{z}$
6	$\frac{a^x}{x}$ \dot{x} given	$\frac{a^x}{a^x - 1}$

Integrals, when found from given increments, are corrected in the very same way as fluents, when found from given fluxions, viz, instead of each several variable quantity in the integral, substituting such a determinate value of them as they are known to have in some particular case; and then subtracting each side of the resulting equation from the corresponding side of the integral, the remaining equation will be the correct state of the integrals.

For an example of the use of the method of increments, suppose it were required to find the sum of any number of terms of the series $1 \cdot 2 + 2 \cdot 3 + 3 \cdot 4 \text{ &c}$,

Let x be the number of the terms,
and z the sum of them.

Then, by the progression of the series, the last, or the x term, is xx , and the next term after that will be x^2 , that is $\tilde{z} = xx$, where $x = 1$. Hence the integral is

$z = \frac{1}{3} x^2 x = \frac{1}{3} x \cdot x + 1 \cdot x + 2$, which is the sum of x terms of the given series. So if the number of terms x be 10, this becomes $\frac{1}{3} \cdot 10 \cdot 11 \cdot 12 = 440$, which is the sum of 10 terms of the given series $1 + 2 + 3 + 4 + \dots + 10 = 55$. Or, when $x = 100$, the sum of 100 terms of the same series is $\frac{1}{3} \cdot 100 \cdot 101 \cdot 102 = 100 \cdot 101 \cdot 34 = 343400$.

Again, to find the sum z of n terms of the series

$$\frac{1}{1 \cdot 3 \cdot 5} + \frac{1}{3 \cdot 5 \cdot 7} + \frac{1}{5 \cdot 7 \cdot 9} \text{ &c.}$$

Here the n th term is $\frac{1}{2n-1 \cdot 2n+1 \cdot 2n+3}$.

Put $x = 2n - 1$; then is $x = 2n - 2$, and the n th term is $\frac{1}{x(x+2)} = \frac{1}{xx}$; and the $n + 1$ th term or \tilde{z} is

$\frac{1}{\frac{1}{xx}}$; the general integral of which is $z = \frac{-1}{2x^2} = \frac{-1}{4x^2}$.

But this wants a correction; for when $n = 0$, then $x = -1$, and the sum $z = 0$, and the integral becomes z or $0 = \frac{-1}{4 \cdot 1 \cdot 3} = \frac{-1}{12}$; that is $-\frac{1}{12}$ is the correction, which being subtracted, the correct state of the integrals becomes $z = \frac{1}{12} - \frac{1}{4x^2} = \frac{1}{12} - \frac{1}{4 \cdot 2n+1 \cdot 2n+3}$, which

is the sum of n terms of the proposed series. And when n is infinite, the latter fraction is nothing, and the sum of the infinite series, or the infinite number of the terms, is accurately $\frac{1}{12}$.

When $n = 100$, the sum of 100 terms of the series becomes $z = \frac{1}{12} - \frac{1}{4 \cdot 201 \cdot 203} = \frac{1}{12} - \frac{1}{163212}$.

For more ample information and application on this science, see Emerson's Increments, Taylor's Methodus Incrementorum, and Stirling's Summatio et Interpolatio Scierium.

INCURVATION of the Rays of Light. See LIGHT, and REFRACTION.

INDEFINITE, Indeterminate, that which has no certain bounds, or to which the human mind cannot affix any. Descartes uses the word, in his Philosophy, instead of infinite, both in numbers and quantities, to signify an inconceivable number, or number so great, that an unit cannot be added to it; and a quantity so great, as not to be capable of any addition. Thus, he says, the stars, visible and invisible, are in number indefinite, and not, as the ancients held, infinite; and that quantity may be divided into an indefinite number of parts, not an infinite number.—Indefinite is now commonly used for indeterminate, number or quantity, that is, a number or quantity in general, in contradistinction from some particular known and given one.

INDETERMINED, or INDETERMINATE, in Geometry, is understood of a quantity, which has no certain or definite bounds.

INDETERMINATE Analysis, that particular branch of analysis which treats of the solution of indeterminate problems.

INDETERMINATE Problem, is that which admits of innumerable different solutions, and sometimes perhaps only

of a great many different answers; otherwise called an unlimited problem. In problems of this kind the number of unknown quantities concerned, is greater than the number of the conditions or equations by which they are to be found; from which it happens, that generally some other conditions or quantities are assumed, to supply the defect, which being taken at pleasure, give the same number of answers as varieties in those assumptions. As, if it were required to find two square numbers whose difference shall be a given quantity d . Here, if x^2 and y^2 denote the two squares, then will $x^2 - y^2 = d$, by the question, which is only one equation, for finding two quantities. Now by assuming a third quantity z , so that $z = x + y$ the sum of the two roots; then is $x = \frac{z^2 - d}{2z}$, and $y = \frac{z^2 - d}{2z}$, which are the two roots, having the difference of their squares equal to the given quantity d , and are expressed by means of an assumed quantity z ; so that there will be as many answers to the question, as there can be taken values of the indeterminate quantity z , that is, innumerable.

Again, If it were required to divide 25 into two such parts, that one of them may be divisible by 2, and the other by 3. Then, putting one of the parts sought = $2x$, and the other = $3y$, we shall have $2x + 3y = 25$; one equation as before with two unknown quantities. By reduction, $x = \frac{25 - 3y}{2}$; from which we may conclude in the first place, that $3y$ must be less than 25; and consequently y is less than 8. By division, $x = 12 - y + \frac{1-y}{2}$; from which it is evident that $1 - y$, or rather $y - 1$, must be divisible by 2. Let us therefore assume a third quantity z , such that $y - 1 = 2z$; and we get $y = 2z + 1$; so that $x = 12 - 2z - 1 - z = 11 - 3z$. Now since y cannot be greater than 8, we must not substitute any numbers for z which would make $2z + 1$ greater than 8. Consequently z must be less than $\frac{7}{2}$; that is to say, z cannot be taken greater than 3; for which reasons, are obtained the following answers:

- 1 If $z = 0$; then $y = 1$, and $x = 11$.
- 2 If $z = 1$; then $y = 3$, and $x = 8$.
- 3 If $z = 2$; then $y = 5$, and $x = 5$.
- 4 If $z = 3$; then $y = 7$, and $x = 2$.

Hence, and from the equation it appears, that the two parts sought are i. 22 + 3, ii. 16 + 9, iii. 10 + 15, iv. 4 + 21, the several sums of which are evidently the number given 25.

Diophantus was the first writer on indeterminate problems, viz, in his Arithmetic or Algebra, which was first published in 1575 by Xilander, and afterwards in 1621 by Bachet, with large commentary, and many additions to it. His book is wholly upon this subject; whence it has happened, that such kind of questions have been called by the name of Diophantine problems. Fermat, Descartes, Frenicle in France, and Wallis and others in England, particularly cultivated this branch of algebra, on which they held a correspondence, proposing difficult questions to each other; an instance of which are those two curious ones, proposed by M. Fermat, as a challenge to all the mathematicians of Europe, viz, 1st, To find a cube number which added to all its aliquot parts shall make a square number; and 2d, To find a square number which added to a 1 its aliquot parts shall make

a cubic number; which problems were answered after several ways by Dr. Wallis, as well as some others of a different nature. See the letters that passed between Dr. Wallis, the lord Brouncker, Sir Kenelm Digby, &c, in the doctor's Works; and the Works of Fermat, which were collected and published by his son. Most authors on algebra have also treated more or less on this part of it, but more especially Kersey, Prestet, Ozanam, Kirkby, &c. But afterwards, mathematicians seemed to have forgotten such questions, if they did not even despise them as useless, when Euler drew their attention by some excellent compositions, demonstrating some general theorems, which had only been known by induction. M. Lagrange has also taken up the subject, having resolved very difficult problems in a general way, and discovered more direct methods than heretofore. The 2d volume of the French translation of Euler's Algebra contains an elementary treatise on this branch of analysis, and, with Lagrange's additions, an excellent theory of it; treating very generally of indeterminate problems, of the first and second degree, of solutions in whole numbers, of the method of indeterminate coefficients, &c. Also, much in the same way were such indeterminate problems treated by the Indian algebraists; as may be seen by the account of their algebra given in my Tracts, vol. 2, pa. 151, &c.

Finally, Mr. John Leslie has given, in the 2d volume of the Edinburgh Philos. Transactions, an ingenious paper on the resolution of indeterminate problems, resolving them by a new and general principle. "The doctrine of indeterminate equations," says Mr. Leslie, "has been seldom treated in a form equally systematic with the other parts of algebra. The solutions commonly given are devoid of uniformity, and often require a variety of assumptions. The object of this paper is to resolve the complicated expressions which we obtain in the solution of indeterminate problems, into simple equations, and to do so, without framing a number of assumptions, by help of a single principle, which, though extremely simple, admits of a very extensive application."

"Let $a \times b$ be any compound quantity equal to another, $c \times d$, and let m be any rational number assumed at pleasure; it is manifest that, taking equimultiples, $a \times mb = c \times md$. If therefore we suppose that $a = md$, it must follow that $mb = c$, or $b = \frac{c}{m}$. Thus two equations of a lower dimension are obtained. If these be capable of farther decomposition, we may assume the multiples n and p , and form four equations still more simple. By the repeated application of this principle, a higher equation, admitting of divisors, will be resolved into those of the first order, the number of which will be one greater than that of the multiples assumed.

For example, in the problem, to find two rational numbers, the difference of the squares of which shall be a given number. Let the given number be the product of a and b ; then by the hypothesis, $x^2 - y^2 = ab$; but these compound quantities admit of an easy resolution, for $(x+y) \times (x-y) = a \times b$. If therefore we suppose $x \times y = ma$, we shall obtain $x - y = \frac{b}{m}$; where m is arbitrary, and if rational, x and y must also be rational. Hence the resolution of these two equations gives the values of x and y , the numbers sought, in terms of m ; viz,

$$x = \frac{m^2a + b}{2m}, \text{ and } y = \frac{m^2a - b}{2m}.$$

INDEX, in Arithmetic, is the same with what is otherwise called the characteristic or the exponent of a logarithm; being that which shows of how many places the absolute or natural number belonging to the logarithm consists, and of what nature it is, whether an integer or a fraction; the index being less by 1 than the number of integer figures in the natural number, and is positive for integer or whole numbers, but negative in fractions, or in the denominator of a fraction; and in decimals, the negative index is 1 more than the number of ciphers in the decimal, after the point, and before the first significant figure; or, still more generally, the index shows how far the first figure of the natural number is distant from the place of units, either towards the left hand, as in whole numbers, or towards the right, as in decimals; these opposite cases being marked by the correspondent signs + and -, of opposite affections, the sign - being set over, the index, and not before it, because it is this index only which is understood as negative, and not the decimal part of the logarithm. Thus, in this logarithm 2·4234097, the figures of whose natural number are 2651, the 2 is the index, and being positive, it shows that the first figure of the number must be two places removed from the units place, or that there will be three places of integers, the number of these places being always 1 more than the index; so that the natural number will be 2651. But if the same index be negative, thus -2·4234097, it shows that the natural number is a decimal, and that the first significant figure of it is Number. Logarithm. in the 2d place from units, or 2651 - - 3·4234097 that there is one cipher at the 2651 - - 2·4234097 beginning of the decimal, being 26·51 - - 1·4234097 1 less than the negative index; 2·651 - - 0·4234097 and consequently that the natural number of the logarithm in this case is 02651. Hence, 02651 - - 1·4234097 by varying the natural number, with respect to the decimal 002651 - - 2·4234097 places in it, as in the former of the two columns here annexed, the index of their logarithm will vary as in the 2d column.

Mr. Townley introduced a peculiar way of noting these indices, when they become negative, or express decimal figures, which is now much in use, especially in the logsines and tangents, &c, viz, by taking, instead of the true index, its arithmetical complement to 10; so that, in this way, the logarithm 2·4234097 is written 8·4234097. For the addition and subtraction of indices, see LOGARITHM.

INDEX of a *Globe*, is a little stile fitted on to the north-pole, and turning round with it, pointing out the divisions of the hour-circle.

INDEX of a *Quantity*, in Arithmetic and Algebra, otherwise called the exponent, is the number that shows to what power it is understood to be raised: as in 10^3 , or a^3 , the figure 3 is the index or exponent of the power, signifying that the root or quantity, 10 or a , is raised to the 3d power. See this fully treated under EXPONENT.

INDICTION, or *Roman Indiction*, a kind of epoch, or manner of counting time, among the Romans; containing a cycle or revolution of 15 years. The popes have dated their acts by the year of the indiction, which was fixed to the 1st of January anno domini 813, ever since Charlemagne made them sovereign; before that time, they dated them by the years of the emperors.—At the time of

reforming the calendar, the year 1582 was reckoned the 10th year of the induction; so that beginning to reckon from hence, and dividing the number of years elapsed between that time and this, by 15, the remainder, with the addition of 10, rejecting 15 if the sum be more, will be the year of the induction.

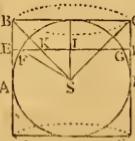

But the induction will be easier found thus: Add 3 to the given year of Christ; divide the sum by 15, and the remainder after the division, will be the year of the induction: if there be no remainder, the induction is 15. In either of these ways, the induction for the year 1795 is 13.

INDIVISIBLES, are those indefinitely small elements, or principles, into which any body or figure may ultimately be divided.—A line is said to consist of points, a surface of parallel lines, and a solid of parallel surfaces: and because each of these elements is supposed indivisible, if in any figure a line be drawn perpendicularly through all the elements, the number of points in that line, will be the same as the number of the elements.

Whence it appears, that a parallelogram, or a prism, or a cylinder, is resolvable into elements, as indivisibles, all equal to each other, parallel, and like or similar to the base; for which reason, one of these elements multiplied by the number of them, that is the base of the figure multiplied by its height, gives the area or content. And a triangle is resolvable into lines parallel to the base, but decreasing in arithmetical progression; so also do the circles, which constitute the parabolic conoid, as well as those which constitute the plane of a circle, or the surface of a cone. In all which cases, as the last or least term of the arithmetic progression is 0, and the length of the figure the same thing as the number of the terms, therefore the greatest term, or base, being multiplied by the length of the figure, half the product is the sum of the whole, or the content of the figure.

And in any other figure or solid, if the law of the decrease of the elements be known, and thence the relation of the sum to the greatest term, which is the base, the whole number of them being the altitude of the figure, then the said sum of the elements is always the content. A cylinder may also be resolved into cylindrical curve surfaces, having all the same height, and continually decreasing inwards, as the circles of the base decrease, on which they insist.

This way of considering magnitudes, is called the method of indivisibles, which is only the ancient method of exhaustions, a little disguised and contracted. And it is found of good use, both in computing the contents of figures in a very short and easy way, as above instances, and in shortening other demonstrations in mathematics; an instance of which may here be given in that celebrated proposition of Archimedes, that a sphere is two-thirds of its circumscribed cylinder. Thus, suppose a cylinder, a hemisphere, and an inverted cone, having all the same base and altitude, and cut by an infinite number of planes all parallel to the base, of which $EFGH$ is one; it is evident that the square of EI , the radius of the cylinder, is every where equal to the square of sr , the radius of the sphere; and also that the square of EI , or of sr , is equal to the sum of the squares of IE and IK , because $IK = IS$; that is, $IE^2 = IE^2 + IK^2$, in every position; but IE is the radius of the cylinder, IE the corre-

sponding radius of the sphere, and IK that of the cone; and the circular sections of these bodies, are as the squares of their radii; therefore the section of the cylinder is every where equal to the sum of the sections of the hemisphere and cone; and, as the number of all those sections, which is the common height of the figures, is the same, therefore all the sections, or elements, of the cylinder, will be equal to the sum of all those of the hemisphere and cone taken together; that is, the cylinder is equal to both the hemisphere and cone; but as the cone itself is equal to one-third part of the cylinder; therefore the hemisphere is equal to the other two-thirds of it.

The method of indivisibles was introduced by Cavalieri, in 1635, in his *Geometria Indivisibilium*. The same was also pursued by Torricelli in his Works, printed 1644: and again by Cavalieri himself in another treatise, published in 1647.

INEQUALITY OPTIC. See *OPTIC Inequality*.

INERTIA of Matter, in Philosophy, is defined by Newton to be a power implanted in all matter, by which it resists any change endeavoured to be made in its actual state; that is, by which it becomes difficult to alter its state, either of rest or motion. This power then, agrees with the vis resistendi, or power of resisting, by which every body endeavours, as much as it can, to persevere in its own state, whether of rest or uniform rectilinear motion; which power is still proportional to the body, or to the quantity of matter in it, the same as the weight, or gravity of the body; and yet it is quite different from, and even independent of the force of gravity, and would be and act just the same if the body were devoid of gravity. Thus, a body by this force resists the same in all directions, upwards, or downwards, or obliquely; whereas gravity acts only downwards.

Bodies only exert this power in changes brought in their state by some vis impressa, or force impressed on them. And the exercise of this power is, in different respects, both resistance and impetus; resistance, so far as the body opposes a force impressed on it to change its state; and impetus, as the same body endeavours to change the state of the resisting obstacle. *Phil. Nat. Princ. Math. lib. 1.*

Inertia, the same great author elsewhere observes, is a passive principle, by which bodies persist in their motion or rest, and receive motion, in proportion to the force impressing it, and resist as much as they are resisted. See *RESISTANCE*.

INERTIAE Vis. See *VIS Inertiae*.

INFINITE, is applied to quantities which are either greater or less than any assignable ones. In which sense it differs but little from the terms *Indefinite* and *Indeterminate*. Thus, an

INFINITE, or *Infinitely great line*, denotes only an indefinite or indeterminate line; or a line to which no certain bounds or limits are prescribed.

INFINITE Quantities. Though the idea of magnitude infinitely great, or such as exceeds any assignable quantity, does include a negation of limits, yet such magnitudes are not all equal among themselves; but besides infinite length, and infinite area, there are no less than three several sorts of infinite solidity; all of which are quantities *sui generis*; and those of each species are in given proportions.—Infinite length, or a line infinitely long, may be considered, either as beginning at a point, and so infinitely extended one way; or else both ways from the same point.—As to infinite surface or area, any right line infinitely

extended both ways on a plane infinitely extended every way, divides that plane into two equal parts, one on each side of the line. But if from any point in such a plane, two right lines be infinitely extended, making an angle between them; the infinite area, intercepted between these infinite right lines, is to the whole infinite plane, as that angle is to 4 right angles. And if two infinite and parallel lines be drawn at a given distance on such an infinite plane, the area intercepted between them will be likewise infinite; but yet it will be infinitely less than the whole plane; and even infinitely less than the angular or sectoral space, intercepted between two infinite lines, that are inclined, though at never so small an angle; because in the one case, the given finite distance of the parallel lines diminishes the infinity in one of the dimensions; whereas in a sector, there is infinity in both dimensions. And thus there are two species of infinity in surfaces, the one infinitely greater than the other.

In like manner there are species of infinites in solids, according as only one, or two, or as all their three dimensions, are infinite; which, though they be all infinitely greater than a finite solid, yet are they in succession infinitely greater than each other.—Some farther properties of infinite quantities are as follow: the ratio between a finite and infinite quantity, is an infinite ratio.—If a finite quantity be multiplied by an infinitely small one, the product will be an infinitely small one; but if the former be divided by the latter, the quotient will be infinitely great.—On the contrary, a finite quantity being multiplied by an infinitely great one, the product is infinitely great; but the former divided by the latter, the quotient will be infinitely little.—The product or quotient of an infinitely great or an infinitely small quantity, by a finite one, is respectively infinitely great, or infinitely little.—An infinitely great multiplied by an infinitely little, is a finite quantity; but the former divided by the latter, the quotient is infinitely infinite.—The mean proportional between infinitely great, and infinitely little, is finite.

Arithmetick of INFINITES. See ARITHMETIC. Also Wallis's treatise on this subject; and another by Emerson, at the beginning of his Conic Sections; also Bulfiard's treatise *Arithmetica Infinitorum*.

INFINITE Decimals, such as do not terminate, but go on without end; as $3\overline{3}3 \&c = \frac{1}{3}$, or $1\overline{4}2857 \&c = \frac{7}{9}$. See REPETEND.

INFINITELY Infinite Fractions, or all the powers of the fractions whose numerator is 1; which are all together equal to unity, as is demonstrated by Dr. Wood, in Hook's Philos. Coll. No 3, pa. 45; where some curious properties are deduced from the same.

INFINITE Series, a series considered as infinitely continued to the number of its terms. See SERIES.

INFINITE-SIMALS, are certain infinitely or indefinitely small parts; as also the method of computing by them.—In the method of infinitesimals, the element by which any quantity increases or decreases, is supposed to be infinitely small, and is generally expressed by two or more terms, some of which are infinitely less than the rest, which being neglected as of no importance, the remaining terms form what is called the Difference of the proposed quantity. The terms that are neglected in this manner, as infinitely less than the other terms of the element, are the very same which arise in consequence of the acceleration, or retardation, of the generating motion, during the infinitely small time in which the element is

generated; so that the remaining terms express the element that would have been produced in that time, if the generating motion had continued uniform. Therefore, those differences are accurately in the same ratio to each other, as the generating motions or fluxions. And hence, though in this method, infinitesimal parts of the elements are neglected, the conclusions are accurately true without even an infinitely small error, and agree precisely with those that are deduced by the method of fluxions.

But however safe and convenient this method may be, some will always scruple to admit infinitely little quantities, and infinite orders and infinitesimals, into a science that boasts of the most evident and accurate principles, as well as of the most rigid demonstrations. In order to avoid such suppositions, Newton considers the simultaneous increments of the flowing quantities as finite, and then investigates the ratio which is the limit of the various proportions which those increments bear to each other, while he supposes them to decrease together till they vanish; which ratio is the same with the ratio of the fluxions. See MacLaurin's Fluxions, in the Introduc. pa. 39 &c, also art. 495 to 502.

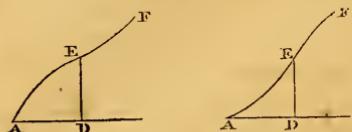

INFLAMMABILITY, that property of bodies by which they kindle, or catch fire.

INFLECTION, in Optics, called also Diffraction, and Deflection of the rays of light, is a property of them, by reason of which, when they come within a certain distance of any body, they are either bent from the body, or towards it; being a kind of imperfect reflection or refraction. Some writers ascribe the first discovery of this property to Grimaldi, who published an account of it, in his treatise *De Lumine, Coloribus, et Iride*, printed in 1666. But Dr. Hooke also claims the discovery of it, and communicated his observations on this subject to the Rôyal Society, in 1672. He shows that this property differs both from reflection and refraction; and that it seems to depend on the unequal density of the constituent parts of the ray, by which the light is dispersed from the place of condensation, and rarefied or gradually diverged into a quadrant; and this deflection, he observes, is made towards the superficies of the opaque body perpendicularly. Newton discovered, by experiments, this inflection of the rays of light; which may be seen in his Optics.

M. Labire observed, that when we look at a candle, or any luminous body, with our eyes nearly shut, rays of light are extended from it, in several directions, to a considerable distance, like the tails of comets. The true cause of this phenomenon, which has exercised the sagacity of Descartes, Rohault, and others, seems to be, that the light passing among the eyelashes, in this situation of the eye, is inflected by its near approach to them, and therefore enters the eye in a great variety of directions. He also observes, that he found that the beams of the stars being observed, in a deep valley, to pass near the brow of a hill, are always more refracted than if there were no such hill, or the observation was made on the top of it; as if the rays of light were bent down into a curve, by passing near the surface of the mountain.

Point of INFLECTION, or of *contrary flexure*, in a curve, is the point or place in the curve where it begins to bend or turn a contrary way; or which separates the concave part from the convex part, and lying between the two; or where the curve changes from-concave to convex, or from convex to concave, on the same side of the curve; such as the point E in the annexed figures; where the former of

the two is concave towards the axis AD from A to E, and convex from E to F; but, on the contrary, the latter figure is convex from A to E, and concave from E to F.

There are various ways of finding the point of inflection; but the following, which is new, seems to be the simplest and easiest of all. From the nature of curvature it is evident that, while a curve is concave towards an axis, the fluxion of the ordinate decreases, or is in a decreasing ratio, with regard to the fluxion of the absciss; but, on the contrary, that the said fluxion increases, or is in an increasing ratio to the fluxion of the absciss, where the curve is convex towards the axis; hence it follows that those two fluxions are in a constant ratio at the point of inflection, where the curve is neither concave nor convex. That is, if $x = AD$ the absciss, and $y = DE$ the ordinate, then \dot{x} is to \dot{y} in a constant ratio, or $\frac{\dot{y}}{\dot{x}}$ or $\frac{dy}{dx}$ is a constant quantity. But constant quantities have no fluxion, or their fluxion is equal to nothing; so that in this case the fluxion of $\frac{\dot{y}}{\dot{x}}$ or of $\frac{dy}{dx}$ is equal to nothing. And hence we have this general rule: viz,

Put the given equation of the curve into fluxions; from which equation of the fluxions find $\frac{\dot{y}}{\dot{x}}$ or $\frac{dy}{dx}$; then take the fluxion of this ratio or fraction, and put it equal to 0 or nothing; and from this last equation find also the value of the same $\frac{\dot{y}}{\dot{x}}$ or $\frac{dy}{dx}$; then put this latter value equal to the former, which will be an equation from whence, and the first given equation of the curve, x and y will be determined, being the absciss or ordinate answering to the point of inflection in the curve.

Or, putting the fluxion of $\frac{\dot{y}}{\dot{x}}$ equal to 0, that is,

$\frac{\ddot{y} - \dot{x}\ddot{y}}{\dot{x}^2} = 0$, or $\ddot{y} - \dot{x}\ddot{y} = 0$, or $\ddot{y} = \dot{x}\ddot{y}$, or $\dot{x} : \ddot{y} :: \ddot{x} : \ddot{y}$, that is, the 2d fluxions have the same ratio as the 1st fluxions, which is a constant ratio; and therefore if x be constant, or $\dot{x} = 0$, then shall $\ddot{y} = 0$ also; which gives another rule, viz: Take both the 1st and 2d fluxions of the given equation of the curve, in which make both \dot{x} and $\ddot{y} = 0$, and the resulting equations will determine the values of x and y , or absciss and ordinate to the point of inflection.

For example, if it be required to find the point of inflection in the curve whose equation is $ax^3 = a^2y + x^2y^2$. Now the fluxion of this is $2ax\dot{x} = a^2\dot{y} + 2xy\dot{x} + x^2\ddot{y}$, which gives $\frac{\dot{x}}{\ddot{y}} = \frac{a^2 + x^2}{2ax - 2xy}$. Then the fluxion of this again made = 0, gives $2x\dot{x}(ax - xy) = (a^2 + x^2) \cdot (ax - y\dot{x} - xy)$; and this gives again $\frac{\dot{x}}{\ddot{y}} = \frac{a^2 + x^2}{a^2 - x^2} \times \frac{x}{a - y}$. Lastly, this

value of $\frac{\dot{x}}{\ddot{y}}$ put = the former, gives

$$\frac{a^2 + x^2}{a^2 - x^2} \cdot \frac{x}{a - y} = \frac{a^2 + x^2}{2x} \cdot \frac{1}{a - y}; \text{ and hence } 2x^2 = a^2 - x^2, \text{ or } 3x^2 = a^2, \text{ and } x = a/\sqrt[3]{3}, \text{ the absciss.}$$

Hence also, from the original equation,

$$y = \frac{ax^2}{a^2 + x^2} = \frac{\frac{1}{3}a^2}{\frac{4}{3}a^2} = \frac{1}{4}a, \text{ the ordinate to the point of inflection sought.}$$

When the curve has but one point of inflection, it will be determined by a simple equation, as above; but when there are several points of inflection, by the curve bending several times from the one side to the other, the resulting equation will be of a degree corresponding to them, and its roots will determine the absciss or ordinates to the same. Other methods of determining the points of inflection in curves, may be seen in most books on the doctrine of fluxions.

To know whether a curve be concave or convex towards any point assigned in the axis; find the value of \ddot{y} at that point; then if this value be positive, the curve will be convex towards the axis, but if it be negative, it will be concave.

INFORMED Stars, or INFORMS Stella, are such stars as have not been reduced into any constellation; otherwise called Sporades.—A great many of this kind were left by the ancient astronomers; but Hevelius and some others of the moderns have provided for the greater part of them, by making new constellations. And I think that the later celestial globes made in England, have the constellations contrived to include the old unformed stars.

INGEEN. See **ENGINEER**.

INGRESS, in Astronomy, the sun's entrance into one of the signs, especially Aries.

INNOCENTS Day, a feast celebrated on the 28th day of December, in commemoration of the infants said to be murdered by Herod.

INORDINATE Proportion, is where the order of the terms compared, is disturbed or irregular. As, for example, in two ranks of numbers, three in each rank, viz, in one rank, - - - 2, 3, 9, and in the other rank - - - 8, 24, 36, which are proportional, the former to the latter, but in a different order, viz, - - 2 : 3 :: 24 : 36, and - - 3 : 9 :: 8 : 24, then, casting out the mean terms in each rank, it concluded that - - - 2 : 9 :: 8 : 36, that is, the first is to the 3d in the first rank,

as the first is to the 3d in the 2d rank.

INSCRIBED Figure, is one that has all its angular points touching the sides of another figure in which the former is said to be inscribed.

INSCRIBED Hyperbola, is one that lies wholly within the angle of its asymptotes; as the common or conical hyperbola doth.

INSTANT, otherwise called a moment, an infinitely small part of duration, or in which we perceive no succession, or which takes up the time of only one idea in our mind. It is a maxim in mechanics, that no natural effect can be produced in an instant, or without some definite time; also that the greater the time, the greater the effect. And hence may appear the reason, why a burthen seems lighter to a person, the faster he carries it; and why, the faster a person slides or skates on the ice, the less liable it is to break, or bend.

INSTITUTE is a name which has lately been substituted for academy or school. When royalty was lately abolished in France, the several royal academies were abolished, and were all condensed into one general academy, under the name of the

National INSTITUTE, or New Academy of Arts and Sciences. This academy was founded on a decree of the new government constitution in the year 1795. It consists of 268 members, half of whom reside in Paris, the other half in the departments; and to them are added 24 foreigners, as honorary members. The academy is divided into 3 classes, each class into sections, each section containing 12 members.

1st Class. Mathematics and natural philosophy. This class is divided into 10 sections. 1. Mathematics. 2. Mechanical arts. 3. Astronomy. 4. Experimental philosophy. 5. Chemistry. 6. Natural history. 7. Botany. 8. Anatomy and animal history. 9. Medicine and surgery. 10. Animal economy, and the veterinary science.

2d Class. Morality and politics. This class consists of 6 sections. 1. Analysis of sensations and ideas. 2. Morals. 3. Legislation. 4. Political economy. 5. History. 6. Geography.

3d Class. Literature and the fine arts, consisting of 8 sections. 1. Universal grammar. 2. Ancient languages. 3. Poetry. 4. Antiquities. 5. Painting. 6. Sculpture. 7. Architecture. 8. Music.

For each class a particular room in the Louvre is appropriated. No person can be a member of two classes at the same time: but a member of one class may be present at the meetings of any other. Each class prints, yearly, an account of its transactions.

Four times a-year public meetings are held, when the three classes meet together. At the end of each year, they give a circumstantial account to the legislative body, of the progress made in that year in the arts and sciences. The prizes given annually by each class, are published at certain times. The sums requisite for the support of the institution, are decreed yearly by the legislative body, on a requisition made by the executive directory.

The first 48 members were chosen by the executive directory, to whom the choice of the remaining members was confided. To the members resident in Paris is reserved the choice, both of the department and foreign members. On a vacancy in any class, three candidates are named by the class, for the choice of the body at large. Each class is to have, at its place of meeting, a collection of the products, both of nature and art, and a library, according to its particular wants. The regulations of the institution, with respect to the times of meeting, and its employments, are to be drawn up by the body at large, and laid before the legislative assembly.

INSULATE, or **INSULATED**, a term applied to a column or other edifice, which stands alone, or free and detached from any adjacent wall, &c., like an island in the sea.

INSULATED, in Electricity, is a term applied to bodies that are supported by electrics, or non-conductors; so that their communication with the earth, by conducting substances, is interrupted.

INSURANCE, the same as **ASSURANCE**; which see.

INTACTÆ are right lines to which curves do continually approach, and yet can never meet them, more usually called **Asymptotes**.

INTEGERS, are whole numbers, as contra-distinguished from fractions. Integers may be considered as numbers which refer to unity, as a whole to a part.

INTEGRAL Number, an integer; not a fraction.

INTEGRAL Calculus, in the New Analysis, is the reverse of the differential calculus, and is the finding the integral

from a given differential; being similar to the inverse method of fluxions, or the finding the fluent to a given fluxion.

The rules for the integration of differentials, like those for the extraction of roots, are established by inspection of the direct process by which, from given functions, differentials are derived: thus, the differential of x^m or $d(x^m)$, is $mx^{m-1}dx$; therefore, from $mx^{m-1}dx$, the integral may be found from this process: increase the index $m-1$, or power of the variable quantity, by unity or 1, and divide by the index so increased, and by the differential of the variable quantity, for the integral required. Let d^{-1} , be the sign of the operation by which the integral is obtained, or the reverse of that operation which d indicates; then will $d^{-1}(mx^{m-1}dx) = x^m$; or, $d^{-1}d(x^m) = x^m$. Also, $d^{-1}(x^{\frac{m}{n}}dx) = \frac{x^{\frac{m+1}{n}}}{\frac{m+1}{n}}$; or $\frac{nx^{\frac{m}{n}}}{\frac{m+1}{n}} = x^{\frac{m+1}{n}}$. Again the integrals

of ax^dx , e^xdx ; are a^x , e^x ; and are obtained on the very same grounds of inspection as the above.

The differentials of $a + bx$, $\bar{a} + bx$, $\bar{a}' + bx$, &c., or $d(a + bx)$, $d(\bar{a} + bx)$, $d(\bar{a}' + bx)$, &c. are dbx , $d\bar{b}x$, $d\bar{b}'x$, &c. Hence inversely, the integrals are $d^{-1}(dbx)$, $d^{-1}(d\bar{b}x)$, $d^{-1}(d\bar{b}'x)$ &c.; where it is to be noted, that the constant quantities a , \bar{a} , \bar{a}' , &c., are the corrections of the integrals; and are determined in the same manner as those in the inverse method of fluxions, from the particular nature of the problem under discussion.

It may be here observed, that as in the analysis of finites, any quantity may be raised to any degree or power; but vice versa, the root cannot be extracted out of any number required: so in the analysis of infinites, any variable or flowing quantity may be differenced, but vice versa, any differential cannot be integrated. And as, in the analysis of finites, we are not yet arrived at a method of extracting the roots of all equations, so neither has the integral calculus arrived at its perfection: and as in the former we are obliged to have recourse to approximation, so in the latter we have recourse to infinite series, where we cannot attain to a perfect integration. For the several authors on this calculus, see **FLUXIONS**.

'**INTEGRANT Parts**', in **Philosophy**, are the similar parts of a body, or parts of the same nature with the whole; as filings of iron are the integrant parts of iron, having the same nature and properties with the bar or mass they were filed off from.

INTENSITY, or **INTENSION**, in **Physics**, is the degree or rate of the power or energy of any quality; as heat, cold, &c. The intensity of qualities, as gravity, light, heat, &c., vary in the reciprocal ratio of the squares of the distances from the centre of the radiating quality.

INTERCALARY Day, denotes the odd day inserted in the leap-year. See **BISSEXTILE**.

INTERCEPTED Axis, in curves, the same with what is otherwise called the absciss or abscissa.

INTERCOLUMNATION, or **INTERCOLUMNIA**, is the space between column and column, which is always to be proportional to the height and bulk of the columns. From a medium, some authors have laid down, the following proportions: in the Tuscan order, the intercolumnation to be 4 diameters of the body of the column below; in the Doric 3, in the Ionic 2½, in the Corinthian 2¼, and in the Composite 1½.

INTEREST, is a sum reckoned for the loan or for-

bearance of another sum, or principal, lent for, or due at, a certain time, according to some certain rate or proportion; being estimated usually at so much per cent, or by the 100. This forms a particular rule in arithmetic. The highest legal interest now allowed in England, is after the rate of 5 per cent. per annum, or the 20th part of the principal for the space of a year, and so in proportion for other times, either greater or less: except in the case of pawnbrokers, to whom it has lately been made legal to take a much higher interest, for one of the worst and most destructive purposes that can be suffered in any state.

Interest is either Simple or Compound.

Simple Interest, is that which is counted and allowed upon the principal only, for the whole time of forbearance.—The sum of the principal and interest is called the amount.

As the interest of any sum, for any time, is directly proportional to the principal sum and time; therefore the interest of 1 pound for one year being multiplied by any proposed principal sum, and by the time of its forbearance, in years and parts, will be its interest for that time. That is,

r = the rate of interest of 1*l.* per annum,

p = any principal sum lent,

t = the time it is lent for, and

a = the amount, or sum of principal and interest;

then is prt = the interest of the sum p , for the time t , at the rate r ; and consequently $p + prt = p \times (1 + rt) = a$, is the amount of the same for that time. And from this general formula, other theorems can easily be deduced for finding any of the quantities above-mentioned; which collected all together, will be as follow:

1st, $a = p + prt$ the amount,

2d, $p = \frac{a}{1 + rt}$ the principal,

3d, $r = \frac{a - p}{pt}$ the rate,

4th, $t = \frac{a - p}{pr}$ the time.

For Example, let it be required to find, in what time any principal sum will double itself, at any rate of simple interest. In this case we may use the 1st theorem $a = p + prt$, in which the amount a must be $= 2p$, or double the principal, i. e. $p + prt = 2p$; and hence $t = \frac{1}{r}$; where r being the interest of 1*l.* for one year, it follows that the time of doubling at simple interest, is equal to the quotient of any sum divided by its interest for one year. So that, if the rate of interest be 5 per cent. then $100 \div 5 = 20$, is the time of doubling.—Or the 4th theorem immediately gives $t = \frac{a - p}{pr} = \frac{2p - p}{pr} = \frac{1}{r}$.

For some compendious tables and rules for computing the interest on money, see my small book of Arithmetic.

Compound Interest, called also *Interest-upon-Interest*, is that which is counted, not only on the principal sum lent, but also for its interest, as it becomes due, at the end of each stated time of payment.

Though it be not lawful to lend money at compound interest, yet in purchasing annuities, pensions, &c., and leases in reversion, it is usual to allow compound interest to the purchaser for his ready money; and therefore it is necessary to understand this subject.

Besides the quantities concerned in simple interest, viz, the principal p , the rate or interest of 1*l.* for 1 year r , the

amount a , and the time t , there is another quantity employed in compound interest, viz, the ratio of the rate of interest, which is the amount of 1*l.* for 1 time of payment, and which here let be denoted by R , viz, $R = 1 + r$. Then, the particular amounts for the several times may be thus computed, viz, As 1 pound, is to its amount for any time, so is any proposed principal sum, to its amount for the same time; i. e.

$1l. : R :: p : pr$ the 1st year's amount,

$1l. : R :: pr : pr^2$ the 2d year's amount,

$1l. : R :: pr^2 : pr^3$ the 3d year's amount,

and so on.

Therefore in general, $pr^t = a$, is the amount for the t year, or t time of payment. Whence the following general theorems are deduced:

1st, $a = pr^t$ the amount,

2d, $p = \frac{a}{R^t}$ the principal,

3d, $R = \sqrt[t]{\frac{a}{p}}$ the ratio,

4th, $t = \frac{\log. of a - \log. of p}{\log. of R}$ the time.

From which any one of the quantities may be found, when the rest are given.

For example, suppose it were required to find, in how many years any principal sum will double itself, at any proposed rate of interest. In this case must be employed the 4th theorem, where a will be $= 2p$, and then it is

$$t = \frac{1 - a}{\log. R} = \frac{1 - 2p}{\log. R} = \frac{\log. 2}{\log. R}.$$

So if the rate of interest be 5 per cent. per annum; then $R = 1 + .05 = 1.05$, and hence

$$t = \frac{\log. 2}{\log. 1.05} = \frac{.3010300}{.0211893} = 14.2067 \text{ nearly; that is, any sum doubles in } 14 \frac{1}{4} \text{ years nearly, at the rate of 5 per cent. per annum compound interest.}$$

Hence, and from the like question in simple interest, above given, are deduced the times in which any sum doubles itself, at several rates of interest, both simple and compound: viz,

At	At Simple Interest.		At Comp. Interest.
	Years.	Years.	Years.
1	100	69.6603	
2	50	35.0028	
$2\frac{1}{2}$	40	28.0701	
3	$33\frac{1}{3}$	23.4498	
$3\frac{1}{2}$	$28\frac{1}{2}$	20.1488	
4	25	17.6730	
$4\frac{1}{2}$	$22\frac{1}{2}$	15.7473	
5	20	14.2067	
6	$16\frac{2}{3}$	11.8957	
7	$14\frac{1}{3}$	10.2448	
8	$12\frac{1}{2}$	9.0065	
9	$11\frac{1}{3}$	8.0432	
10	10	7.2725	

The following Table will very much facilitate the calculation of the compound interest for any sum, for any number of years, at various rates of interest.

The use of this table, which contains all the powers R^t , to the 20th power, or the amounts of 1*l.* is chiefly to calculate the interest, or the amount, of any principal sum, for any time, not more than 20 years. For example, required to find to how much 5*23l.* will amount in 15 years, at the rate of 5 per cent. per annum compound interest.

In the table, on the line 15, and in the column 5 per cent, is the amount of 1*l.*, viz. 2 078*l.*, this multiplied by the principal - 52*d.* gives the amount - 1087 26*d.* or - - 1087*l.* 5*s.* 3*d.* and therefore the interest is - 56*d.* 5*s.* 3*d.*

The Amount of 1*l.* in any Number of Years.

See ANNUITIES; DISCOUNT; REVERSION; Smart's Tables of Interest; the Philos. Trans. vol. 6, pa. 508; and most books on Arithmetic.

INTERIOR Figure, Angle of. See ANGLE.

INTERIOR Polygon. See POLYGON.

INTERIOR Talus. See TALUS.

INTERNAL Angles, are the angles made within any figure, by the sides of it. In a triangle ABC, the two angles

a and c are peculiarly called internal and opposite, in respect of the external angle CBD, which is equal to them both together.

INTERNAL Angle is also applied to the two angles formed between two parallels, by a line intersecting those parallels, on each side of the intersecting line. Such are the angles a, b, c, d, formed between the parallels EF and GH, on each side of the intersecting line.—The two adjacent internal angles a and b, or c and d, are together equal to two right angles.

INTERNAL and Opposite Angles, is also applied to the two angles a and b, which are respectively equal to the two n and m, called the external and opposite angles. Also the alternate internal angles are equal to each other; viz, a = d, and b = c.

INTERPOLATION, in the modern Algebra, is used for finding an intermediate term of a series, its place in the series being given. The method of interpolation was first invented by Mr. Briggs, and by him applied to the calculation of logarithms, &c, in his *Arithmetica Logarithmica*,

VOL. I.

and, his *Trigonometria Britannica*; where he explains, and fully applies the method of interpolation by differences. His principles were followed by Reginald and Mouton in France, and by Cotes and others in England. Wallis employed the method of interpolation in several parts of his works; as his *Arithmetica of infinites*, and his *Algebra*, for quadratures, &c. The same was also happily applied by Newton in various ways: by it he investigated his binomial theorem, and quadratures of the circle, ellipse, and hyperbola: see Wallis's *Algebra*, chap. 85, &c. Newton also, in lemma 5, lib. 3 Princip. gave a most elegant solution of the problem for drawing a curve line through the extremities of any number of given ordinates; and in the subsequent proposition, he applied the solution of this problem to that of finding, from certain observed places of a comet, its place at any given intermediate time. And Dr. Waring, who adds, that a solution still more elegant, on some accounts, has been since discovered by Mess. Nichol and Stirling, has also resolved the same problem, and rendered it more general, without having recourse to finding the successive differences. *Philos. Trans.* vol. 69, part 1, art. 7. Mr. Stirling indeed pursued this branch as a distinct science, in a separate treatise, viz. *Tractatus de Summatione et Interpolatione Serierum Infinitarum*, in the year 1730.

When the 1st, 2d, or other successive differences of the terms of a series become at last equal, the interpolation of any term of such a series, may be found by Newton's Differential Method. When the algebraic equation of a series is given, the term required, whether it be primary or intermediate one, may be found by the resolution of affected equations; but when that equation is not given, as it often happens, the value of the term sought must be exhibited by a converging series, or by the quadrature of curves. See Stirling, *ut supra*, pa. 86. Meyer, in *Act. Petr.* tom. 2, pa. 180.

A general theorem for interpolating any term is as follows: Let α denote any term of an equidistant series of terms, and a, b, c, \dots the first of the 1st, 2d, 3d, &c, orders of differences; then the term z , whose distance from α is expressed by x , will be this, *viz.* Theorem 1,

$$z = \alpha + xa + x \cdot \frac{x-1}{2} b + x \cdot \frac{x-1}{2} \cdot \frac{x-2}{3} c \text{ &c.}$$

Hence, if any of the orders of differences become equal to one another, or = 0, this series for the interpolated term will break off, and terminate, otherwise it will run out in an infinite series.

Example. To find the 20th term of the series of cubes 1, 8, 27, 64, 125, &c, or 1³, 2³, 3³, 4³, 5³, &c.

Set down the series in a column, and take their continual differences as here annexed, where the 4th differences, and all after it become = 0, also $a = 1$, $a = 7$, $b = 12$, $c = 6$, and $x = 19$; therefore the 20th term sought is barely

A	a
1	1
8	7
27	12
64	6
125	0

$$z = 1 + 19 \times 7 + 19 \times \frac{18}{2} \times 12 + 19 \times \frac{18}{2} \times \frac{17}{3} \times 6 \\ = 1 + 133 + 2052 + 5814 = 8000.$$

Theor. 2. In any series of equidistant terms, a, b, c, d, \dots whose first differences are small; to find any term wanting in that series, having any number of terms given. Take the equation which stands against the number of

4 T

given terms, in the following table; and by reducing the equation, that term will be found.

No. Equations.

$$\begin{array}{l} 1 \quad a - b = 0 \\ 2 \quad a - 2b + c = 0 \\ 3 \quad a - 3b + 3c - d = 0 \\ 4 \quad a - 4b + 6c - 4d + e = 0 \\ 5 \quad a - 5b + 10c - 10d + 5e - f = 0 \\ 6 \quad a - 6b + 15c - 20d + 15e - 6f + g = 0 \\ \text{&c.} \end{array}$$

$$n \quad a - nb + n \cdot \frac{n-1}{2} c - n \cdot \frac{n-1}{2} d, \text{ &c.} = 0;$$

where it is evident that the coefficients in any equation, are the unities of a binomial $1 + 1$ raised to the power denoted by the number of the equation.

Example. Given the logarithms of 101, 102, 104, and 105; to find the log. of 103.

Here are 4 quantities given; therefore we must take the 4th equation, $a - 4b + 6c - 4d + e = 0$, in which it is the middle quantity or term c that is to be found, because 103 is in the middle among the numbers 101, 102, 104, 105; then that equation gives the value of c as follows,

$$\text{viz } c = \frac{4(b+d) - (a+e)}{6}.$$

Now the logs. of the given numbers will be thus:

$$2\cdot0043214 = a$$

$$2\cdot0086002 = b$$

$$2\cdot0170333 = d$$

$$2\cdot0211893 = e$$

$$4\cdot0256335 = b + d$$

4

$$16\cdot1025340 = 4 \cdot (b + d)$$

$$\text{subtr. } 4\cdot0255107 = \quad a + e$$

$$6\cdot12\cdot0770233$$

$$2\cdot0128372 \text{ the log. of 103.}$$

Theor. 3. When the terms $a, b, c, d, \text{ &c.}$ are at unequal distances from each other; to find any intermediate one of these terms, the rest being given.

Let $p, q, r, s, \text{ &c.}$ be the several distances of those terms from each other; then let

$$B = \frac{b-a}{p}; C = \frac{b_1 - B}{p+q}; D = \frac{c_1 - C}{p+q+r}; E = \frac{b_1 - D}{p+q+r+s};$$

$$B_1 = \frac{c-b}{q}; C_1 = \frac{B_2 - B_1}{q+r}; D_1 = \frac{c_2 - C_1}{q+r+s};$$

$$B_2 = \frac{d-c}{r}; C_2 = \frac{B_3 - B_2}{r+s};$$

$$B_3 = \frac{e-d}{s};$$

&c. &c. Then the term z , whose distance from the beginning is x , will be

$$z = a + bx + cx \cdot (x-p) + dx \cdot (x-p) \cdot (x-p-q) + ex \cdot (x-p) \cdot (x-p-q-r) + \text{ &c.}$$

to be continued to as many terms as there are terms in the given series.

By this series may be found the place of a comet, or the sun, or any other object at a given time; by knowing the places of the same for several other given times. Other methods of interpolation may be found in the Philos. Trans. number 362; or Stirling's Summation and Interpolation of Series.

INTERSCENDENT, in Algebra, is applied to quantities, when the exponents of their powers are radical quantities. Thus $x^{\sqrt{2}}, x^{\sqrt[3]{a}}$, &c., are intercedent quantities. See FUNCTION.

INTERSECTION, the cutting of one line, or plane, by another; or the point or line in which two lines or two planes cut each other.—The mutual intersection of two planes is a right line. The centre of a circle, or conic section, &c., is in the intersection of two diameters; and the central point of a quadrangle, is the intersection of two diagonals.

INTERSTELLAR, intervening between the stars; a word used by some authors, to express those parts of the universe, that are without and beyond the limits of our solar system.—In the interstellar regions, it is supposed there are several other systems of planets, moving round the fixed stars, as the centres of their respective motions. And if it be true, as it is not improbable, that each fixed star is thus a sun to some habitable orbs, or earths, that move round it, the interstellar world will be infinitely the greatest part of the universe.

INTERTIES, or INTERDUCES, in Architecture, those small pieces of timber which lie horizontally between the summers, or between them and the cell or rising plate.

INTERVAL, in Music, the difference between two sounds, in respect of acute and grave. Authors distinguish several divisions of an interval, as first into Simple and Compound. The

Simple INTERVAL is that without parts, or division; such are the octave, and all that are within it; as the 2d, 3d, 4th, 5th, 6th, and 7th, with their varieties.

Compound INTERVAL consists of several lesser intervals; as the 9th, 10th, 11th, &c., with their varieties.

The simple interval was by the ancients called a diastem, and the compound they called a system.

An interval is also divided into just or true, and into false. The

Just or True INTERVALS, are such as all those above mentioned, with their varieties, whether major or minor.

False INTERVALS, are the diminutive or superfluous ones.

An interval is also divided into the consonance and dissonance; which see.

INTESTINE Motion of the parts of fluids, that which is among its corpuscles or component parts. When the attracting corpuscles of any fluid are elastic, they must necessarily produce an intestine motion; and that, greater or less, according to the degrees of their elasticity and attractive force. For, two elastic particles, after meeting, will fly from each other, with the same degree of velocity with which they met; abstracting from the resistance of the medium. But when, in leaping back from each other, they approach other particles, their velocity will be increased.

INTONATION, in Music, the action of sounding the notes in the scale with the voice, or any other given order of musical tones.—Intonation may be either true or false; either too high or too low, either too sharp or too flat; and then this word intonation attended with an epithet must be understood concerning the manner of performing the notes.

INTRADOS, the interior and lower side, or curve, of an arch. In contradistinction from the extrados, or exterior curve, or line on the upper side of the arch. See my Tracts, vol. 1.

INTRENCHMENT, in Fortification, any work that shelters a post against the attacks of an enemy. It is generally taken for a ditch, or trench with a parapet. Intrenchments are sometimes made of fascines with earth

thrown over them, of gabions, hogsheads, or bags filled with earth, to cover the men from the enemy's fire.

INVERSE, is applied to a manner of working the rule of three, or proportion, which seems to go backward, i.e. reverse or contrary to the order of the common and direct rule: so that, whereas, in the direct rule, more requires more, or less requires less; in the inverse rule, on the contrary, more requires less, or less requires more.—For instance, in the direct rule it is said, If 3 yards of cloth cost 20 shillings, how much will 6 yards cost? the answer is 40 shillings; where more yards require more money, and less yards require less money. But in the inverse rule it is said, If 20 men perform a piece of work in 6 days, in how many days will 40 men perform as much? where the answer is 3 days; and here the more men require the less time, and the fewer men the more time.

INVERSE Method of Fluxions, is the method of finding fluents, from the fluxions being given; and is similar to what the foreign mathematicians call the calculus integralis. See **FLUENTS**.

INVERSE Method of Tangents, is the method of finding the curve belonging to a given tangent; as opposed to the direct method, or the finding the tangent to a given curve.—As, to find a curve whose subtangent is a third proportional to $r - y$ and y , or whose subtangent is equal to the semiordinate, or whose subnormal is a constant quantity. The solution of this problem depends chiefly on the inverse method of fluxions. See **TANGENT**. See also Montucla, v. 3, pa. 164.

INVERSE Proportion, or INVERSE Ratio, is that in which more requires less, or less requires more. As for instance, in the case of light, or heat from a luminous object, the light received is less at a greater distance, and greater at a less distance; so that here more, as to distance, gives less, as to light, and less distance gives more light. This is usually expressed by the term inversely, or reciprocally; as in the case above, where the light is inversely, or reciprocally as the square of the distance; or in the inverse or reciprocal duplicate ratio of the distance.

INVERSION, Invertendo, or by Inversion, by the 14th def. of Euclid, lib. 5, is inverting the terms of a proportion, by changing the antecedents into consequents, and the consequents into antecedents. As in these, $a : b :: c : d$, then by inversion $b : a :: d : c$.

INVESTIGATION, the searching or finding any thing out, by means of certain steps, traces, or ways.

INVOLUTE Figure or Curve, is that which is traced out by the outer extremity of string as it is folded or wrapped upon another figure, or as it is unwound from off it. The involute of a cycloid, is also a cycloid equal to the former, which was first discovered by Huygens, and by means of which he contrived to make a pendulum vibrate in the curve of a cycloid, and so, theoretically at least, vibrate always in equal times, whether the arch of vibration were great or small; which is a property of that curve. See **EVOLUTE**.

INVOLUTION, in Arithmetic and Algebra, is the raising of powers from a given root; as opposed to Evolution, which is the extracting, or developing of roots from given powers. So the involution of the number 3, or its powers, are thus raised:

3^1 or 3^1 or 3 is the 1st power, or root,

3×3 or 3^2 or 9 is the 2d power, or square,

$3 \times 3 \times 3$ or 3^3 or 27 is the 3d power, or cube, and so on.—And hence, to find any power of a given root,

or quantity, let the root be multiplied by itself a number of times which is one less than the number of the index; i.e. once multiplied for the 2d root, twice for the 3d root, thrice for the 4th root, &c.

So also, in algebra, to involve the binomial $a + b$, or raise its powers.

$a + b$ - - - - 1st power, or root

$\frac{a^2 + ab}{a + b}$ - - - -

$a^2 + ab + b^2$ - - - -

$\frac{a^2 + 2ab + b^2}{a + b}$ - - - -

$a^2 + 2a^2b + 2ab^2$ - - - -

$\frac{a^2 + a^3b + ab^2 + b^3}{a + b}$ - - - -

$a^2 + 3a^2b + 3ab^2 + b^3$ - - - -

$a^2 + 3a^2b + 3ab^2 + b^3$ - - - -

And in like manner for any other quantities, whatever the number of their terms may be. But compound algebraic quantities are best involved by the **BINOMIAL Theorem**; which see.

Simple quantities are involved, by raising the numerical coefficients to the given power, and the literal quantities are raised by multiplying their indices by that of the root; that is, the raising of powers is performed by the multiplication of indices, the same as the multiplication of logarithms. Thus,

The 2d power of a is a^2 .

The 2d power of $2a^2$ is $2^2 a^{2 \times 2}$ or $4a^4$.

The 3d power of $3a^2b^3$ is $3^3 a^6b^9$.

The 3d power of $a^{\frac{1}{2}}b^{\frac{2}{3}}$ is $a^{\frac{3}{2}}b^2$.

The n th power of $a^m c^n$ is $a^{mn} c^{pn}$ or $(a^m c^n)^n$.

INWARD Flanking Angle, in Fortification, is that made by the curtain and the razant flanking line of defence.

JOINTS, in Architecture, are the separations between the stones or bricks; which may be filled with mortar, plaster, or cement.

JOINT, in Carpentry, &c., is applied to several manners of assembling, setting, or fixing pieces of wood together. As by a mortise joint, a dove-tail joint, &c.

Universal JOINT, in Mechanics, an excellent invention of Dr. Hooke, adapted to all kinds of motions and flexures; of which he has given a large account in his *Cutterian Lectures*, printed in 1678. This seems to have given occasion to the gimbals used in suspending the sea compass; the mechanism of which is the same with that of Desaguliers's rolling lamp.

JOINT-LIVES, are such as continue during the same time, or that exist together. See **LIFE-Annuities**.

JOISTS, or **JOISTS**, those pieces of timber framed into the girders and summers, and on which the boarding of floors is laid. They are of various kinds: as, 1. **Common Joists**, being those which are framed level or flush with the upper surface of the girders, but are seldom of equal depth. 2. **Trimming Joists**, those which are framed into two other joists, that other joists may be framed into them, where the opening is made for a stair-case, or a chimney hearth. 3. **Binding Joists**, those which are laid across from girder to girder, and about 3 or 4 inches lower than their upper surface, in order that other joists, called 4. **Bridging Joists**, may be laid over them parallel to the girders. 5. **Ceiling Joists**, which are turned into the binding joists, and are generally made slender, having but little weight to support.—The chief or flooring joists, should be about 8 inches deep, the common breadth of a

deal board ; their breadth more or less, according to their length, viz, from 2 to 4 inches broad, or different lengths from 6 to 12 feet.

" JONES (WILLIAM), F. R. S. a very eminent mathematician, was born at the foot of Bodafon mountain [Mynydd Bodafon] in the parish of Llanfihangel tre'r Bard, in the Isle of Anglesey, North Wales, in the year 1675. His Father's name was John George, his surname being the proper name of his father. For it is a custom in several parts of Wales for the proper name of the father to become the surname of his children. John George the father was commonly called Sion Siors of Llanbabo, to which place he moved, and where his children were brought up. Accordingly our author, whose proper name was William, took the surname of Jones from the proper name of his father, who was a farmer, and of a good family, being descended from Hwfa ap Cynddelw, one of the 15 tribes of North Wales. He gave his two sons the common school education of the country, reading, writing, and accounts, in English, and the Latin Grammar. Harry his second son took to the farming business; but William the eldest, having an extraordinary turn for mathematical studies, determined to try his fortune abroad from a place where the same was but of little service to him. He accordingly came to London, accompanied by a young man, Rowland Williams, afterwards an eminent perfumer in Wych-street. The report in the country is, that Mr. Jones soon got into a merchant's counting house, and so gained the esteem of his master, that he gave him the command of a ship for a West India voyage; and that upon his return he set up a mathematical school, and published his book of Navigation; and that upon the death of the merchant he married his widow: that, lord Macclesfield's son being his pupil, he was made secretary to the chancellor, and one of the deputy tellers of the exchequer:—and they have a story of an Italian wedding, which caused great disturbance in lord Macclesfield's family, but was compromised by Mr. Jones; which gave rise to a saying, 'that Macclesfield was the making of Jones, and Jones the making of Macclesfield.' " The foregoing account of Mr. Jones, I found among the papers of the late Mr. John Robertson, librarian and clerk to the Royal Society, who had been well known to Mr. Jones, and possessed many of his papers.

Mr. Jones having by his industry acquired a competent fortune, lived upon it as a private gentleman for many years, in the latter part of his life, in habits of intimacy with Sir Isaac Newton and others the most eminent mathematicians and philosophers of his time; and died July 3, 1749, at 74 years of age, being one of the vice-presidents of the Royal Society; leaving at his death one daughter, and a son very young, who was the late Sir William Jones, one of the judges in India, and highly esteemed for his great abilities, extensive learning, &c.—Mr. Jones's publications were,

1. A new Compendium of the whole Art of Navigation, &c; in small Svo, London, 1702. This is a neat little piece, and dedicated to the Rev. Mr. John Harris, the author of the Lexicon Technicum, or Universal Dictionary of Arts and Sciences, in whose house Mr. Jones says he composed his book.

2. Synopsis Paliniorum Mathesos : or a New Introduction to the Mathematics, &c; Svo, London, 1706; being a very neat and useful compendium of all the mathematical sciences, in about 300 pages.

His papers in the Philos. Trans. are the following:

3. A Compendious Disposition of Equations for exhibiting the relations of Goniometrical Lines; vol. 44, pa. 560.

4. A Tract on Logarithms; vol. 61, pa. 455.

5. Properties of the Conic Sections, deduced by a compendious method; vol. 63, pa. 340.

In all these works of Mr. Jones, a remarkable neatness, brevity, and accuracy, every where prevail. He seemed to delight in a very short and comprehensive mode of expression and arrangement; in so much that, sometimes what he has contrived to express in two or three pages, would occupy a little volume in the ordinary style of writing.

Mr. Jones, it is said, possessed the best mathematical library in England; scarcely any book of that kind but what was there to be found. He had collected also a great quantity of manuscript papers and letters of former mathematicians, which have often proved useful to writers of their lives, &c. After his death, these were dispersed, and fell into different persons' hands; many of them, as well as of Mr. Jones's own papers, were possessed by the late Mr. John Robertson, before mentioned, at whose death I purchased a considerable quantity of them. From such collections as these it was that Mr. Jones was enabled to give that first and elegant edition, in 4to, 1711, of several of Newton's papers, that might otherwise have been lost, entitled, Analysis per quantitatum Series, Fluxiones, ac Differentias: cum Enumeratione Linearum Tertii Ordinis.

IONIC Column, or Order, the 3d of the five orders, or columns, of architecture. The first idea of this order was given by the people of Ionia; who, according to Vitruvius, formed it on the model of a young woman, dressed in her hair, and of an easy elegant shape, as the Doris had been formed on the model of a strong robust man. This column is a medium between the massive and the more delicate orders, the simple and the rich. It is distinguished from the composite, by having none of the leaves of acanthus in its capital; and from the Tuscan, Doric, and Corinthian, by the volutes, or rams' horns, which adorn its capital; and from the Tuscan and Doric, by the chancrels or fluting, in its shaft. The height of this column is 18 modules, or 9-diameters of the column taken at the bottom: indeed at first its height was but 16 modules; but, to render it more beautiful than the Doric, its height was augmented by adding a base to it, which was unknown in the Doric. M. Leclerc makes its entablature to be 4 modules and 10 minutes, and its pedestal 6 modules; so that the whole order makes 28 modules 10 minutes

JOURNAL, in Merchants' Accounts, is a book into which every particular article is posted out of the waste-book, according to the order of time, specifying the debtor and creditor in each account and transaction.

JOURNAL, in Maritime Affairs, is a register kept by the pilot, and others, noticing every thing that happens to the ship, from day to day, and from hour to hour, with regard to the winds, the rhumbs or courses, the knots or rate of running, the rake, soundings, astronomical observations, for the latitudes and longitudes, &c; to enable them to adjust the reckoning, and determine the place where the ship is. In all sea journals, the day, or what is called the 24 hours, is divided into twice 12 hours; those before noon marked A.M. for ante meridiem, and those from noon to midnight marked P.M. post meridiem, or afternoon.

There are various ways of keeping a sea journal, according to the different notions of mariners concerning the articles to be entered. Some writers direct the keeping such a kind of journal as is only an abstract of each day's transactions, specifying the weather, what ships or lands were seen, accidents on board, the latitude, longitude, meridional distance, course, and run: these particulars are to be drawn from the ship's log-book, or from that kept by the person himself. Other authors recommend the keeping only of one account, including the log-book, and all the work of each day, with the deductions drawn from it.

JOURNAL is also used for the title of several books published at stated times; giving accounts and abstracts of the new books that are published, with the new improvements daily made in arts and sciences. The first journal of this kind was, the Journal des Scavans, printed at Paris: the design was set on foot for the ease of such as are too busy, or too indolent, to read the entire books themselves. It seems a ready way of satisfying a man's curiosity, and becoming learned on easy terms: and so useful has it been found, that it has been executed in most other countries, though under a great variety of titles.

Of this kind are the Acta Eruditorum of Leipsic; the Nouvelles de la Republique des Lettres of M. Bayle, &c; the Bibliotheque Universelle, Choise, et Ancienne et Moderne, of M. Leclerc; the Memoirs de Trevoux, &c. In 1692, Juncker printed in Latin, An Historical Treatise of the Journals of the Learned, published in the several parts of Europe; and Wolfius, Struvius, Morhoff, Fabricius, &c, have done something of the same kind.

The Philosophical Transactions of London, and those of Edinburgh; the Memoirs of the Royal Academý of Sciences; those of the Academy of Belles Lettres; the Miscellanea Natura Curiosorum: the Experiments of the Academy del Cimento, the Acta Philo-exoticorum Naturæ et Artis, which appeared from March 1686 to April 1687, and which are a history of the Academy of Bresse; the Miscellanea Berolinensis, or Memoirs of the Academy of Berlin; the Commentaries of the Academy of Petersburg; the Memoirs of the Institute at Bologna; the Acta Literaria Suecicæ; the Memoirs of the Royal Academy of Stockholm, begun in 1740; the Commentarii Societatis Regiae Gottingensis, begun in 1750, &c, &c, are not so properly journals, though they are frequently ranked in the number.

Juncker and Wolfius give the honour of the first invention of journals to Photius. His Bibliotheca, however, is not altogether of the same nature with the modern journals; nor was his design the same. It consists of abridgments and extracts of books which he had read during his embassy in Persia. M. Salo first began the Journal des Scavans at Paris, in 1665, under the name of the Sieur de Hedonville; but his death soon after interrupted the work. The abbé Gallois then took it up, and he, in the year 1674, gave way to the abbé de la Roque, who continued it nine years, and was succeeded by M. Cousin, who carried it on till the year 1702, when the abbé Bignon instituted a new society, and committed the care of continuing the journal to them, who improved and published it under a new form. This society is still continued, and M. de Loyer has had the inspection of the journal; which is no longer the work of any single author, but of a great number. The other French journals are the Memoirs

and Conferences of Arts and Sciences, by M. Dennis, during the years 1672, 1673, and 1674; New Discoveries in all the parts of Physic, by M. de Blegny; the journal of Physic, begun in 1684, and some others, discontinued almost as soon as begun. Rozier's Journal de Physique, begun in July 1771, and continued till, in the year 1780, there were 19 vols. quarto.

The Nouvelles de la Republique des Lettres, News from the Republice of Lettres, were begun by M. Bayle in 1684, and carried on by him till the year 1687, when M. Bayle being disabled by sickness, his friends, M. Bernard and M. de Laroque, took them up, and continued them till 1699. After an interruption of nine years, M. Bernard resumed the work, and continued it till the year 1710. The History of the Works of the Learned, by M. Basnage, was begun in the year 1686, and ended in 1710. The Universal Historical Library, by M. Leclerc, was continued to the year 1693, and contained twenty-five volumes. The Bibliotheque Choise of the same author, began in 1703. The Mercury of France is one of the most ancient journals of that country, and is continued by different persons: the Memoirs of a History of Sciences, and Arts, usually called Memoires des Trevoux, from the place where they are printed, began in 1701. The Essays of Literature reached but to a 12th volume in 1702, 1703, and 1704; these only take notice of ancient authors. The Journal Literaire, by Father Hugo, began and ended in 1705. At Hamburg they have made two attempts for a French journal, but the design failed: an Ephemerides Scavantes has also been undertaken, but that soon disappeared. A Journal des Scavans, by M. Dartis, appeared in 1694, but was discontinued the year following. That of M. Chauvin, begun at Berlin in 1696, held out three years; and an essay of the same kind was made at Geneva. To these may be added, the Journal Literaire begun at the Hague 1715, and that of Verdun, and the Memoires Literaires de la Grande Bretagne by M. de La-roche; the Bibliotheque Angloise, and Journal Britan-nique, which are confined to English books alone. The Italian journals are, that of Abbot Nazari, which continued from 1668 to 1681, and was printed at Rome. That of Venice began in 1671, and ended at the same time with the other: the authors were Peter Moretti and Francis Miletti. The Journal of Parma, by Roberti and Father Bacchini, was declined in 1690, and resumed again in 1692. The Journal of Ferrara, by the abbé de Latorre, began and ended in 1691. La Galeria di Minerva, begun in 1696, is the work of a society of men of letters. Signior Apostolo Zeno, secretary to that society, began another Journal in 1710, under the protection of the grand duke: it is printed at Venice, and several persons of distinction are concerned in it.

The Fasti Euriditi della Biblioteca Volante, were published at Parma. There has appeared since, in Italy, the Giornale dei Letterati.

The principal among the Latin journals, is that of Leipsic, under the title of Acta Eruditorum, begun in 1682: P. P. Manzani began another at Parma. The Nova Literaria Maris Baltici lasted from 1698 to 1708. The Nova Literaria Germaniae, collected at Hamburgh, began in 1703. The Acta Literaria ex Manuscriptis, and the Bibliotheca Curiosa, begun in 1705, and ended in 1707, are the works of Struvius. Messrs. Kuster and Sike, in 1697, began a Bibliotheca Novorum Librorum, and continued it for two

years. Since that time, there have been many Latin journals; such, besides others, is the *Commentarii de Rebus in Scientia Naturali et Medicina gestis*, by M. Ludwig. The Swiss journal, called *Nova Literaria Helvetica*, was begun in 1702, by M. Scheuchzer; and the *Acta Medica Hafnensis*, published by T. Bartholin, make five volumes from the year 1671 to 1679. There are two Low-Dutch journals; the one under the title of *Boockzaal van Europe*, which was begun at Rotterdam in 1692, by Peter Rabbus; and continued from 1702 to 1708, by Sewel and Gavern: the other was conducted by a physician, called Ruiter, who began it in 1710. The German journals of best note are, the *Monathlichen Unterredungen*, which continued from 1689 to 1698. The *Bibliotheca Curiosa*, began in 1704, and ended in 1707, both by M. Tenzel. The *Magazin d'Hambourg*, commenced in 1748: the *Physicalische Belustigungen, or Philosophical Amusements*, begun at Berlin in 1751. The Journal of Hanover began in 1700, and continued for two years by M. Eccard, under the direction of M. Leibnitz, and afterwards carried on by others. The Theological Journal, published by M. Loescher, under the title of *Altes und Neues*, that is, Old and New. A third at Leipsic and Francfort, the authors Mess. Walterk, Krause, and Grosschusius; and a fourth at Hall, by M. Turk.

The English journals are, *The History of the Works of the Learned*, begun at London in 1699. *Censura Temporum*, in 1708. About the same time there appeared two new ones, the one under the title of *Memoirs of Literature*, containing little more than an English translation of some articles in the foreign journals, by M. De Laroche; the other a collection of loose tracts, entitled, *Bibliotheca Curiosa*, or a *Miscellany*. These, however, with some others, are now no more, but are succeeded by the *Annual Register*, which began in 1758; the *New Annual Register*, begun in 1780; the *Monthly Review*, which began in the year 1749, and gives a character of all English literary publications, with the most considerable of the foreign ones: the *Critical Review*, which began in 1756, and is nearly on the same plan: as also the *London Review*, by Dr. Kenrick, from 1775 to 1780; *Mary's Review*, from Feb. 1782, to Aug. 1786; the *English Review*, begun in Jan. 1783; and the *Analytical Review* begun in May 1788, both now extinct. The *Edinburgh Review* begun in 1802, the *Quarterly Review* in 1808, and the *New Quarterly* in 1813, all these published four times a year; also *Tilloch's Philosophical Magazine*, begun 1798; *Nicholson's Philosophical Journal* in 1797, but ended with 1813; and *Thomson's Annals of Literature*; all published monthly. Besides these, we have several monthly pamphlets, called *Magazines*, which, together with a chronological series of occurrences, contain letters from correspondents, communicating extraordinary discoveries in nature and art, with controversial pieces on all subjects. Of these, the principal are those called, the *Gentleman's Magazine*, which began with the year 1731; the *London Magazine*, which began a few months after, and has lately been discontinued; the *Universal Magazine*, which is nearly of as old a date; and best of all the *Monthly Magazine* begun in 1796.

IRIS, another name for the **RAINBOW**; which see.

IRIS also, denotes the striped variegated circle round the pupil of the eye, formed of a dupliciture of the uvea. In different subjects, the iris is of several very different

colours; whence the eye is called grey, or black, &c. In its middle is a perforation, through which appears a small black speck, called the sight, pupil, or apple of the eye, round which the iris forms a ring.

IRIS is also applied to those changeable colours, which sometimes appear in the glasses of telescopes, microscopes, &c.; so called from their similitude to a rainbow.—The same appellation is also given to that coloured spectrum, which a triangular prismatic glass will project on a wall, when placed at a proper angle in the sun-beams.

IRIS Marina, the *Sea-Rainbow*. This elegant appearance is generally seen after a violent storm, in which the sea water has been in vast emotions. The celestial rainbow however has great advantage over the marine one, in the brightness and variety of the colours, and in their distinctness one from the other; for in the sea-rainbow, there are scarce any other colours than a dusky yellow on the part next the sun, and a pale green on the opposite side. The other colours are not so bright, or so distinct, as to be well determined; but the sea-rainbows are more frequent and more numerous than the others: it is not uncommon to see 20 or 30 of them at a time at noon-day.

IRRADIATION, the emission of subtle effluvia, in all directions, like the rays of the sun.

IRRATIONAL Numbers, or *Quantities*, are the same as surds, or such roots as cannot be accurately extracted, being incommensurable to unity. See **SURDS**.

IRREDUCIBLE Case, in Algebra, is used for that case of cubic equations where the root, according to Cardan's rule, appears under an impossible or imaginary form, and yet is real; viz., in the form $x^3 - ax = \pm c$, having $\frac{4}{27}a^3$ greater than $\frac{1}{4}c^2$, or $4a^3$ greater than $27c^2$. Thus, in the equation $x^3 - 15x = 4$, the root, according to Cardan's rule, is $x = \sqrt[3]{(2 + \sqrt{-121})} + \sqrt[3]{(2 - \sqrt{-121})}$, which is in the form of an impossible expression, and yet it is equal to the quantity 4:

$$\text{for } \sqrt[3]{(2 + \sqrt{-121})} = 2 + \sqrt{-1}, \\ \text{and } \sqrt[3]{(2 - \sqrt{-121})} = 2 - \sqrt{-1}, \\ \text{therefore their sum is } x = 4.$$

The other two roots of the equation are also real.

Algebraists, for almost three centuries, have in vain endeavoured to resolve this case, and to bring it under a real form; and the problem is not less celebrated among them, than the squaring of the circle is among geometers. It is to be observed, that, as in some other cases of cubic equations, the value of the root, though rational, is found under an irrational or surd form; because the root in this case is compounded of two equal surds with contrary signs, which destroy each other; as if $x = 2 + \sqrt{3} + 2 - \sqrt{3}$, then $x = 4$. In like manner, in the irreducible case, where the root is rational, there are two equal imaginary quantities, with contrary signs, joined to real quantities; so that the imaginary quantities destroy each other; as in the case above of the root of the equation $x^3 - 15x = 4$, which was found to be $2 + \sqrt{-1} + 2 - \sqrt{-1} = 4$. It is remarkable that this case always happens, viz. one root, by Cardan's rule, in an impossible form, whenever the equation has three real roots, and no impossible ones, but at no time else.

If we were possessed of a general rule for accurately extracting the cube root of a binomial radical quantity, it is evident we might resolve the irreducible case generally, which consists of two such cubic binomial roots. But

the labours of the algebraists, from Cardan's down to the present time, have not been able to remove this difficulty. Dr. Wallis thought that he had discovered such a rule; but, like most others, it is merely tentative, and can only succeed in certain particular circumstances.

It has been sometimes asserted that, in the irreducible case of cubic equation, if the coefficients of all the terms be rational, the equation will have at least one rational root: which may be demonstrated in this manner.

The given equation being $x^3 - ax = c$, where the coefficients a and c are rational.

Let $\pm 2m$ denote one of the roots;

then $\mp m + n\}$ may denote the other two roots.
and $\mp m - n\}$

Hence a or $m^2 - n^2 - 4m^2$ is rational:

but $4m^2$ is rational, therefore $m^2 - n^2$ is rational.

Again, $c = 2m$. ($m^2 - n^2$) is rational:

but $m^2 - n^2$ is rational, therefore $2m$ is rational,
which is one of the roots.

One of the most convenient methods of resolving such cubic equations, is by means of tables of sines, &c. See the article *CUBIC Equations*.

Mr. Maseres, cursor baron of the exchequer, has lately deduced, by a long train of algebraical reasoning, from Newton's celebrated binomial theorem, an infinite series, which will resolve this case, without any mention of either impossible or negative quantities. And I have also discovered several other series which will do the same thing, in all cases whatever; both inserted in the Phil. Trans. See Cardan's Algebra; the articles Algebra, Cubic Equations; Wallis's Algebra, chap. 48; De Moivre in the Appendix to Sanderson's Algebra, pa. 744; Philos. Trans. vol. 68, part 1, art. 42, and vol. 70, pa. 387; and my New Tracts, vol. 2, pa. 98, &c.

IRREGULAR, something that deviates from the common forms or rules. Thus, we say an irregular fortification, an irregular building, &c.

IRREGULAR Figure, in Geometry, whether plane or solid, is that whose sides, as well as angles, are not all equal and similar among themselves.

IRREGULARITIES in the Moon's motion. See *Moon*.

ISAGONE, in Geometry, is sometimes used for a figure consisting of equal angles.

ISLAND, or **ISLE**, a tract of dry land encompassed by water; whether by the sea, a river, or lake, &c. In which sense Island stands contradistinguished from Continent, or terra firma; like Great Britain, Ireland, Jersey, Sicily, Minorca, &c.

Some naturalists imagine that islands were formed at the deluge: others think they have been rent and separated from the continent by violent storms, inundations, and earthquakes; while others are thrown up by volcanoes, or otherwise grow or emerge from the sea.

Varenius thinks most of these opinions true in some instances, and believes that there have been islands produced each of these ways. St. Helena, Ascension, and other steep rocky islands, he supposes have become so, by the sea's overflowing their neighbouring champaigns. By the heaping up huge quantities of sand, &c, he thinks the islands of Zealand, Japan, &c, were formed: Sumatra and Ceylon, and most of the East-India islands, he rather thinks were rent off from the main land, as England probably was from France. It is also certain that some have emerged from the bottom of the sea; as Santorini formerly, and three other isles near it lately; the last in 1707, which

rose from the bottom of the sea, after an earthquake: the ancients had a tradition that Delos rose from the bottom of the sea; and Seneca observes that the island Therasia rose out of the Ægean sea in his time, of which the mariners were eye witnesses; as they have been within these 10 years, in the sea between Norway and Iceland, as also in the Atlantic ocean, where an island has just emerged, near St. Michael's. The late circumnavigators too have made it probable, that many of the South sea islands have had their foundations, of coral rock, gradually increasing, and growing out of the sea.

ISLES, or rather Ailes, in Architecture, the wings or sides of a building.

ISOCHRONAL, or **I SO C H R O N O U S**, is applied to such vibrations of a pendulum as are performed in equal times. Of which kind are all the vibrations of the same pendulum in a cycloidal curve, and in a circle nearly, whether the arc it describes be longer or shorter; for when it describes a shorter arc, it moves so much the slower; and when a long one, proportionally faster.

ISOCHRONAL Line, is that in which a heavy body is supposed to descend with a uniform velocity, or without any acceleration. Leibnitz, in the Act. Erud. Lips. for April 1689, has a discourse on the Linea Isochrona, in which he shows, that a heavy body, with the velocity acquired by its descent from any height, may descend from the same point by an infinite number of isochronal curves, which are all of the same species, differing from one another only in the magnitude of their parameters (such as are all the quadratocubical paraboloids), and consequently similar to one another. He shows also, how to find a line, in which a heavy body descending, shall recede uniformly from a given point, or approach uniformly to it.

ISOMERIA, in Algebra, a term of Vieta, denoting the freeing an equation from fractions; which is done by reducing all the fractions to one common denominator, and then multiplying each member of the equation by that common denominator, that is rejecting it out of them all.

ISOPERIMETRICAL Figures, are such as have equal perimeters, or circumferences. It is demonstrated in geometry, that among isoperimetric figures, that is always the greatest, which contains the most sides or angles. Whence it follows, that the circle is the most capacious of all figures which have the same perimeter with it.—That of two isoperimetric triangles, which have the same base, and one of them two sides equal, and the other unequal; that is the greater whose sides are equal. That of isoperimetric figures, whose sides are equal in number, that is the greatest which is equilateral, and equiangular. Hence arises the solution of that popular problem, To make the hedging or walling, which will fence in a certain given quantity of land, also to fence in any other greater quantity of the same. For let x be one side of the rectangle that will contain the quantity aa of acres; then will $\frac{aa}{x}$ be its other side, and double their sum, viz. $2x + \frac{2aa}{x}$, will be the perimeter of the rectangle: let also bb be any greater number of acres, in the form of a square, then is b one side of it, and $4b$ its perimeter, which must be equal to that of the rectangle; and hence the equation $2x + \frac{2aa}{x} = 4b$, or $x^2 + a^2 = 2bx$, in which quadratic equation the two roots are $x = b \pm \sqrt{(b^2 - a^2)}$, which are the lengths

of the two dimensions of the rectangle, viz, whose area b^2 , is in any proportion less than the square a^2 , of the same perimeter. As, for example, if one side of a square be 10, and one side of a rectangle be 19, but the other only 1; such square and parallelogram will be isoperimetrical, viz, each perimeter 40; yet the area of the square is 100, and of the parallelogram only 19.

Isoperimetrical lines and figures have greatly engaged the attention of mathematicians at all times. The 5th book of Pappus's Collections is chiefly on this subject; where a great variety of curious and important properties are demonstrated, both of planes and solids, some of which were then old in his time, and many new ones of his own. Indeed it seems he has here brought together, into this book, all the properties relating to isoperimetrical figures then known, and their different degrees of capacity.

The analysis of the general problem concerning figures that, among all those of the same perimeter, produce maxima and minima, was given by Mr. James Bernoulli, from computations that involve 2d and 3d fluxions. And several enquiries of this nature have been since prosecuted in like manner, but not always with equal success. Mr. Maclaurin, to vindicate the doctrine of fluxions from the imputation of uncertainty or obscurity, has illustrated this subject, which is considered as one of the most abstruse parts of this doctrine, by giving the resolution and composition of these problems by first fluxions only; and in a manner that suggests a synthetic demonstration, serving to verify the solution. See Maclaurin's Fluxions, pa. 486; Analysis Magni Problematis Isoperimetrici Act. Erud. Lips. 1701, pa. 213; Mem. Acad. Scien. 1705, 1706, 1718; and the works of John Bernoulli, tom. 1, pa. 202, 208, 424, and tom. 2, pa. 235; where is contained what he and his brother James published on this problem. Mr. John Bernoulli, in his first paper, considered only two small successive sides of the curve; whereas the true method of resolving this problem in general, requires the considering three such small sides, as may be perceived by examining the two solutions.

M. Euler has also published, on this subject, many profound researches, in the Petersburg commentaries; and there was printed at Lausanne, in 1744, a pretty large work upon it, entitled, Methodus inventiendi lineas curvas, maximis minimis proprieitate gaudentes: sive Solutio problematis isoperimetrici in latissimo sensu accepti.—M. Cramer too, in the Berlin Memoirs for 1752, has given a paper, in which he proposes to demonstrate in general, what can be demonstrated only of regular figures in the elements of geometry, viz, that the circle is the greatest of all isoperimetric figures, regular or irregular—M. Lhuillier has some elementary problems on isoperimeters, in his Polygometry; and a very considerable tract on this subject is given in my Course of Mathematics, vol. 3, pa. 31—53.

On this head, see also Simpson's Tracts, pa. 98; and the Philos. Trans. vol. 49 and 50.

ISOSCELES Triangle, is a triangle that has two sides equal. In the 5th prop. of Euclid's 1st book, which prop. is usually called the pons asinorum, or asses bridge, it is demonstrated, that the angles, a and b , at the base of the isosceles triangle, are equal to each other; and that if the equal sides be produced, the two angles, c and d ,

below the base, will also be equal. It is also inferred, that every equilateral triangle is also equiangular.

Other properties of this figure are, that the perpendicular AP , from the vertex to the base, bisects the base, the vertical angle, and also the whole triangle. And that if a line be drawn from the vertex to any point in the base, the square of this line, together with the rectangle of the segments of the base, will be equal to the square of one of the equal sides of the triangle. Also, if the vertical angles of two isosceles triangles be equal, the two triangles will be equiangular.

ISTHMUS, in Geography, a narrow neck or slip of land, that joins two other large tracts together, and separating two seas, or two parts of the same sea. The most remarkable isthmuses are, that of Panama or Straits of Darien, connecting north and south America; that of Suez, which joins Asia and Africa; that of Corinth, or Peloponnesus, in the Morea; that of Crim Tartary, otherwise called Taurica Chersonesus; that of the Peninsula Romania and Erisso, or the isthmus of the Thracian Chersonesus, 12 furlongs broad, and which Xerxes undertook to cut through. The ancients had several designs of cutting the isthmus of Corinth, which is a rocky hillock, about 10 miles' over; but without effect, the invention of sluices being not then known. There have also been attempts for cutting the isthmus of Suez, to make a communication between the Mediterranean and the Red-sea.

JULIAN Calendar, is that depending on, and connected with the Julian Year and account of time; so called from Julius Caesar, by whom it was established. See CALENDAR.

JULIAN Epoch, is that of the institution of the Julian reformation of the calendar, which began the 46th year before Christ.

JULIAN Period, is a cycle of 7980 consecutive years, invented by Julius Scaliger, from whom it was named; though some say his name was Joseph Scaliger, and that it was called the Julian period, because he made use of Julian years. This period is formed by multiplying continually together the three following cycles, viz, that of the sun of 28 years, that of the moon of 19 years, and that of the indiction of 15 years; so that this epoch, though but artificial or feigned, is yet of good use; in that every year within the period is distinguishable by a certain peculiar character; for the year of the sun, moon, and indiction, will not be the same again till the whole 7980 years have revolved. Scaliger fixed the beginning of this period 764 years before the creation, or rather the period naturally reduces to that year, taking the numbers of the three given cycles as he then found them; and accounting 3950 years from the creation to the birth of Christ, this makes the 1st year of the Christian era answer to the 4714th year of the Julian period; therefore, to find the year of this period, answering to any proposed year of Christ, to the constant number 4713, add the given year of Christ, and the sum will be the year of the Julian period: thus, to 4713 adding 1791, the sum 6504 is the year of this period for the year of Christ 1791. Hence the first revolution of the Julian period will not be completed till the year of Christ 3267, after which a new revolution of this period will commence.

But the year of the Julian period may be found for any time, from the numbers of the three cycles that compose it, without making use of the given year of Christ; thus, multiply the

numbers { 4845 } respectively by { sun,
{ 4200 } the year of the { moon,
{ 6916 } induction :
then add the three products together, and divide the sum
by 7980; so shall the remainder, after division, be the year
of the Julian period corresponding to the given years
of the other three cycles. Thus, for the year 1791, the years
of the solar, lunar, and induction cycles, are 8, 6, and 9;
therefore multiplying by these, &c, according to the rule,
thus

4845	4200	6916
8	6	9
38760	25200	62244
	38760	
	62244	
7980) 126204 (15	7980	
	46404	
	39900	

remains 6504 the year of the Julian period.

JULIAN Year, is the old account of the year, established by Julius Cæsar, and consisted of 365½ days. This year continued in use in all Europe, till it was superseded in most parts by the new or Gregorian account, in the year 1582. In England however it continued to be used till the year 1752, when it was abolished by act of parliament, and eleven days added to the account, to bring it up to the new style. In Russia, the old or Julian year and style are still in use.

JULY, the 7th month of the year, consisting of 31 days; about the 21st of which the sun usually enters the sign Ζ leo. It was so named by Mark Antony, from Julius Caesar, who was born in this month.

JUNGIUS (JOACHIM), a learned German, who was born at Lübeck. He studied at Giessen, where he applied to mathematics and metaphysics, and wrote Latin tragedies. He was some time professor of mathematics, but quitting that station, he studied physic at Augsburg, and took his doctor's degree at Padua. He was esteemed a very learned man, being author of several valuable works, and died at Hamburg, in 1657, where his Geometria Empyrica was published, in 1669, 4to.

Dr. Birch (Hist. Royal Soc. vol. 2, pa. 342) says, Jun-
gius was rector of the Gymnasium at Hamburg. In the
original draught of a letter of Mr. (afterwards Dr.) John
Pell, to Sir Charles Cavendyshe, dated at Amsterdam,
1644, that eminent mathematician recommends Dr. Jun-
gius and John Adolphus Tassius, corrector of the same
Gymnasium, to the acquaintance of Sir Charles, who was
then at Hamburg, as both mathematicians, of whose abili-
ties and worth he had a great opinion. He remarked
that Jungius had many things in print. As Apodictica,
and Apodidactica. That Tassius had, two years before,
reprinted Jungius's Geometria Empyrica in 5 sheets of
paper, but without diagrams: that Tassius was a very
courteous, affable, open man; Jungius a little more re-
served. He added, "The most barbarous nations had
something to worship; and there are few men that have
not some idol, some man or woman, whom they esteem
and admire above all the rest of mankind; and Jungius
is mine. For I esteem of men more or less, as I find them
more or less rational; and therefore having seen something
of Jungius's writing, wherein he seemed to me to make a
true and better use of his reason, and to manage that di-

vine instrument of instruments, with more dexterity and
skill, than any other son of Adam, all other writers must
pardon me, if I profess to expect more solidity in Jungius's
writings, than in any other man now living. If you find
but the one half of what I imagine to be in Jungius, you
will never be able to relish any other modern philos-
opher." Sir Charles Cavendyshe accordingly, in a letter to
Mr. Pell, without a date, but received by the latter at
Amsterdam, Sept. 22, 1644, mentions his having seen
Jungius, whom he found very free, and who, he observed,
preferred the analytics of the antients before Vieta's by
letters, as being more subject to errors and mistakes,
though more facile and quick of dispatch.

Mr. Oldenburg, secretary of the Royal Society, read to
the Society a Latin letter to him, from Dr. Martin Fogelius
of Hamburg, dated there Jan. 1608, containing an ac-
count of some manuscripts left by Jungius, concerning
motion, and Apollonius de Locis Planis, in 2 books; of
the former of which subjects were transmitted the chief
heads, and the method observed in the latter: the writer
of which letter expressed his inclination to publish those
writings, if encouragement were given to him. It does not
appear that any thing was done in consequence of it, but
the latter may be seen in the letter-book of the Royal So-
ciety, vol. 3, pa. 5.

JUNO, a name given to one of the small newly-discovered planets, viz, that found by M. Harding in the year 1804. See ASTRONOMY, HARDING, EXCENTRICITY, &c.

JUPITER, 4, one of the superior planets, remarkable
for its splendour, being the brightest of all, except sometimes
the planet Venus, and is much the largest of all the
planets. Jupiter is situated between Mars and Saturn,
being the 9th in order of the primary planets from the sun.
His diameter is more than 10 times the diameter of the earth,
and therefore his magnitude more than 1000 times.
His real diameter is 89170 miles. His annual revolution
about the sun is almost 12 years, viz, 4350 days 14 hours
39 minutes 2 seconds, going at the rate of more than 25
thousand miles per hour, at the mean distance of 490
millions of miles; and he revolves about his own axis in
the short space of 9 hours 56 minutes, by which his equatorial
parts are carried round at the amazing rate of 26
thousand miles per hour, which is about 25 times faster
than the like parts of our earth revolve.

Jupiter is surrounded by faint substances, called zones
or belts, in which so many changes appear, that they are
generally ascribed to clouds: for some of them have been
first interrupted and broken, and then have vanished en-
tirely. They have sometimes been observed of different
breadths, and afterwards have all become nearly of the
same breadth. Large spots have been seen in these belts;
and when belt vanishes, the contiguous spots disappear
with it. The broken ends of some belts have often been
observed to revolve in the same time with the spots; only
those nearer the equator in somewhat less time than those
nearer the poles; perhaps on account of the sun's greater
heat near the equator, which is parallel to the belts and
course of the spots. Several large spots, which appear
round at one time, grow oblong by degrees, and then di-
vide into two or three round spots. The periodical time
of the spots near the equator is 9 hours 50 minutes, but
of those near the poles 9 hours 56 minutes. See Dr. Smith's
Optics, § 1105 and 1109.

The axis of Jupiter is so nearly perpendicular to his
orbit, that he has no sensible change of seasons; which is

a great advantage, and considered as wisely ordered by the Author of Nature. For, if the axis of this planet were inclined any considerable number of degrees, just so many degrees round each pole would in their turn be almost 6 years together in darkness. And, as each degree of a great circle on Jupiter contains about 706 miles, it is easy to judge what vast tracts of land would be rendered uninhabitable by any considerable inclination of his axis.

The difference between the equatorial and polar diameters of Jupiter, is upwards of 6000 miles; the former being to the latter as 13 to 12: so that his poles are more than 3000 miles nearer his centre than the equator is. This happens from his quick motion round his axis; for the fluids, together with the light particles, which they can carry or wash away with them, recede from the poles which are at rest, towards the equator where the motion is quickest, until there be a sufficient number accumulated to make up the deficiency of gravity lost by the centrifugal force, which always arises from a quick motion round an axis: and when the deficiency of weight or gravity of the particles is made up by a sufficient accumulation, there is then an equilibrium, and the equatorial parts rise no higher.

Jupiter's orbit is $1^{\circ} 18' 56''$ inclined to the ecliptic. The place of his aphelion $11^{\circ} 8' \text{ of } \Delta$, the place of his ascending node $7^{\circ} 29' \text{ of } \varpi$, and that of his south or descending node $7^{\circ} 29' \text{ of } \varphi$. The eccentricity of his orbit is $\frac{1}{2}$ of his mean distance from the sun.

The sun appears to Jupiter but the 48th part so large as to us; and his light and heat are in the same small proportion, but compensated by the quick returns of them, and by 4 moons, some of them larger than our earth, which revolve about him; so that there is scarce any part of this huge planet but what is, during the whole night, enlightened by one or more of these moons, except his poles, whence only the farthest moons can be seen, and where their light is not wanted, because the sun constantly circulates in or near the horizon, and is very probably kept in view of both poles by the refraction of Jupiter's atmosphere, which, if it be like ours, has certainly refractive power enough for that purpose. This planet, seen from its nearest moon, appears 1000 times as large as our moon does to us; increasing and waning in all her monthly shapes, every $42\frac{1}{2}$ hours. The periods, distances, in semidiameters of Jupiter, and angles of the orbits of these moons, seen from the earth, are as follow:

No.	Periods round Jupiter.	Distances.	Angles of orbits.
1	$1^{\circ} 18' 36''$	$5\frac{2}{3}$	$3' 55''$
2	3 13 15	9	6 14
3	7 3 59	$14\frac{1}{2}$	9 58
4	16 18 30	$25\frac{1}{3}$	17 30

The three nearest moons of Jupiter fall into his shadow, and are eclipsed in every revolution: but the orbit of the 4th satellite is so much inclined, that it passeth by its opposition to Jupiter, without falling into his shadow, two years in every six. By these eclipses, astronomers have not only discovered that the sun's light takes up 8 minutes of time in coming to us; but have also by them determined the longitudes of places on this earth, with greater certainty and facility, than by any other method yet invented. The outermost of these satellites will appear nearly as large as the moon does to us. See M. Laplace's Theory of Jupiter's Satellites, in the Mémoires de l'Acad. and in the Connoissance des Temps for 1792, pa. 273.

The English astronomer Mr. Pound long since observed, that the irregularities of the three interior satellites of Jupiter were repeated in a period of 437 days; and this observation is found to be just to the present time. For the following curious circumstance has now been established, viz,

247 revolutions of the 1st occupy	437 ^d	3 ^h	44 ^m
123 - -	2d	-	437 3 42
61 - -	3d	-	437 3 36
26 - -	4th	-	435 14 16

This naturally led mathematicians to examine their motions, and see in what manner their relative positions, or configurations, as they are called, corresponded to this period; and it is found, that the mean longitude of the 1st satellite,

$$\begin{aligned} &\text{minus 3 times that of the 2d,} \\ &\text{plus 2 times that of the 3d,} \\ &\text{always amounted to 180 degrees.} \end{aligned}$$

This requires that the mean motion of the first, added to twice that of the 3d, shall be equal to 3 times the mean motion of the 2d.—This correspondence of the mean motions is of itself a singular thing, and the odds or chance against its probability seems infinitely great; and when we add to this the particular positions of the satellites in any one moment, which is necessary for the above constant relation of their longitudes, the improbability of the coincidence, as a thing quite fortuitous, becomes infinitely greater. Doubts were at first entertained of the coincidence, because it was not indeed accurate to a second. The result of the investigation is curious. When the consequences of mutual gravitation are followed out, we find, that though neither the primitive motions of projection, nor the points of the orbit from which the satellites were projected, were precisely such as suited these observed relations of their revolutions, and their contemporaneous longitudes; yet, if they differed from them only by very minute quantities, the mutual gravitations of the satellites would in time bring them into those positions, and those states of mean motion, that would induce the observed relations; and when they are once reduced, they will be continued for ever.

Though there be 8 primary planets below Jupiter, yet an eye placed on his surface would never perceive any of them; unless perhaps as spots passing over the sun's disc, when they happen to come between the eye and the sun. The parallax of the sun, viewed from Jupiter, will scarce be sensible, being not much above 20 seconds; and the sun's apparent diameter in Jupiter, but about 6 minutes. Dr. Gregory adds, that an astronomer in Jupiter would easily distinguish two kinds of planets, four nearer him, viz his satellites, and two more remote, viz the sun and Saturn; the former however will fall vastly short of the sun in brightness, notwithstanding the great disproportion in the distances and apparent magnitude.

JURIN (Dr. JAMES), a very distinguished person in several walks of literature, particularly medicine, mathematics, and philosophy, which he cultivated with equal success. He was secretary of the Royal Society in London, as well as president of the College of Physicians there, at the time of his death, which happened March 22, 1750. Doctor Jurin was author of several ingenious compositions; particularly An Essay upon Distinct and Indistinct Vision; printed at the end of the 2d volume of Dr. Smith's System of Optics: also several controversial papers; against Michelotti, on the momentum of running

waters ; against Robins, on distinct vision ; against Bishop Berkeley, on the doctrine of fluxions ; and against the partisans of Leibnitz, on the forces of moving bodies ; &c. His papers inserted in the Philos. Trans. are the following :

1. On the Suspension of Water in Capillary Tubes : vol. 30, pa. 739.—2. Observations on the Motion of Running Water : pa. 748.—3. On an old Roman Inscription : pa. 813.—4. A Discourse on the Power of the Heart : pa. 863 and 929.—5. On the Specific Gravity of Human Blood, pa. 1000.—6. Defence of his Doctrine of the Power of the Heart against the Objections of Dr. Keill : pa. 1039.—7. On the Action of Glass Tubes upon Water and Quicksilver : pa. 1083.—8. On the Specific

Gravity of Solids when weighed in Water : vol. 31, pa. 223.—9. On the Motion of Running Water, against Michelotti : vol. 32, pa. 179.—10. Remarkable Instance of the Small-pox : vol. 32, pa. 191.—11. Inoculated and Natural Small-pox compared : vol. 32, pa. 213.—12. On Meteorological Diaries : vol. 32, pa. 422.—13. On the Measure and Motion of Running Water : vol. 41, pa. 5 and 65.—14. Meteorological Observations in Charles-Town : vol. 42, pa. 491.—15. On the Action of Springs : vol. 43, pa. 46.—16. On the Force of Bodies in Motion : pa. 423.—17. Dynamic Principles, or Meteorological Principles of Mechanics : vol. 66, pa. 103.

K E I

KÆSTNER (), a celebrated German mathematician; died about the end of the year 1800, in the 80th year of his age, having filled the chair of professor of mathematics and natural philosophy in the university of Göttingen from the year 1756, being as it were the Patriarch of European mathematicians. From his pen we have several elementary works on different branches of the mathematics, which have all met with great success ; his Elements of Arithmetic, of Plane and Spherical Trigonometry, and of Perspective, having passed through five editions between the years 1758 and 1794. He was one of those who have the most materially contributed to introduce a sound method into the study of mathematics. The catalogue of his different works fills above nine pages in the last edition of Meusel's German Literature. Among the number are the translations of several important works from the French, the English, and the Low-Dutch. His History of the Mathematics, in 4 volumes, may be considered as a descriptive catalogue of his own library : for he possessed a precious collection of all the most rare and valuable works in the mathematical departments.

Kæstner's mode of life was somewhat singular : during the latter years of his life he never went abroad except on Sundays, when he regularly attended the sermons at his parish-church, and on the days when the Royal Literary Society at Göttingen held their sittings. A few months before his death, he was afflicted with a paralytic stroke in his right hand ; but so assiduous and indefatigable was he in the prosecution of his studies, that he began to write with his left ; and so continued till the time of his decease.

KANG HI, one of the greatest princes of China, who reigned in the 17th century. He, wishing to have a chart of his empire and its environs, employed for that purpose several European missionaries, to whose labour we are indebted for the grand chart of China, first published in 1735, in France, by M. Duhalde ; and since with some corrections by Danville. He also caused to be translated into the Chinese and Tartar languages, several treatises on astronomy, and some astronomical tables ; as also the Elements of Euclid, which he very much admired. Verbiest calculated for him, in 1683, a table of all the eclipses of the sun and moon that would happen in the course of

2000 years. See Astron. Europea by Verbiest. The invention of logarithms, and the tables of sines, delighted him beyond all expression : he soon caused a small edition of them to be made, that he always carried about with him, and which after his death were sent as a curiosity to the library of the jesuits at Lyons. He also very much admired the European art of writing ; but his ears being accustomed to the grave music and monotony of his country, he could never relish the lively and animating music of the Europeans ; what we call harmony seemed to him only a confused noise. He had several sons, who were instructed in most of the European sciences, at their own request, thus imitating the example given them by their father.

KEILL (Dr. JOHN), an eminent mathematician and philosopher, was born at Edinburgh in 1671, and studied in the university of that city. His genius leading him to the mathematics, he made a great progress under David Gregory the professor there, who was one of the first that had embraced and publicly taught the Newtonian philosophy. In 1694 he followed his tutor to Oxford, where, being admitted of Balliol-college, he obtained one of the Scotch exhibitions in that college. It is said he was the first who taught Newton's principles by the experiments on which they are founded : and this it seems he did by an apparatus of instruments of his own providing ; by which means he acquired a great reputation in the university. The first public specimen he gave of his skill in mathematical and philosophical knowledge, was his Examination of Dr. Burnet's Theory of the Earth : with Remarks on Mr. Whiston's New Theory ; which appeared in 1698. These theories were defended by their respective authors ; which drew from him, in 1699, An Examination of the Reflections on the Theory of the Earth, together with A Defence of the Remarks on Mr. Whiston's New Theory. Dr. Burnet was a man of great humanity, moderation, and candour ; and it was therefore supposed that Keill had treated him too roughly, considering the great disparity of years between them. Keill however left the doctor in possession of that which has since been thought the great characteristic and excellence of his work ; and though he disclaimed him as a philosopher, yet allowed him to be a man of a fine imagination.

The year following, Dr. Millington, Sedleian professor of natural philosophy in Oxford, who had been appointed physician to King William, substituted Keill as his deputy, to read the lectures in the public school. This office he discharged with great reputation; and, the term of enjoying the Scotch exhibition at Balliol-college now expiring, he accepted an invitation from Dr. Aldrich, dean of Christ-church, to reside there.

In 1701 he published his celebrated treatise, entitled *Introductio ad Veram Physicam*, which is supposed to be the best and most useful of all his performances. The first edition of this book contained only fourteen lectures; but to the second, in 1705, he added two more. This work was deservedly esteemed, both at home and abroad, as the best introduction to the *Principia*, or the new mechanical philosophy, and was reprinted in different places; also a new edition in English was printed at London in 1736, at the instance of M. Maupertuis, who was then in England.

Being made Fellow of the Royal Society, he published, in the *Philos. Trans.* 1708, a paper on the Laws of Attraction, and its physical principles: and being offended at a passage in the *Acta Eruditorum* of Leipsic, where Newton's claim to the first invention of the method of fluxions was called in question, he warmly vindicated that claim against Leibnitz. In 1709 he went to New-England as treasurer of the Palatines; and soon after his return in 1710, he was chosen Savillian professor of astronomy at Oxford. In 1711, being attacked by Leibnitz, he entered the lists with that mathematician, in the dispute concerning the invention of fluxions. Leibnitz wrote a letter to Dr. Hans Sloane, then secretary to the Royal Society, requiring Keill, in effect, to make him satisfaction for the injury he had done him in his paper relating to the passage in the *Acta Eruditorum*; he protested, that he was far from assuming to himself Newton's method of fluxions; and therefore desired that Keill might be obliged to retract his false assertion. On the other hand, Keill desired that he might be permitted to justify what he had asserted; and he made his defence to the approbation of Newton, and other members of the Society. A copy of this was sent to Leibnitz; who, in a second letter, remonstrated still more against Keill's want of candour and sincerity; adding, that it was not fit for one of his age and experience to engage in a dispute with an upstart, who acted without any authority from Newton, and desiring that the Royal Society would enjoin him to silence. On this, a special committee was appointed; who, after examining the facts, concluded their report with "declaring Newton to be the inventor of fluxions: and that Mr. Keill, in asserting the same, had been in no respect injurious to M. Leibnitz." The whole proceedings on this matter may be seen in Collins's *Commercial Epistolicum*, with many valuable papers of Newton, Leibnitz, Gregory, and other mathematicians. In the mean time Keill behaved himself with great firmness and spirit; which he also showed afterwards in a Latin epistle, written in 1720, to John Bernoulli, mathematical professor at Basil, on account of the same usage shown to Newton: in the title-page of which he put the arms of Scotland, viz., a thistle, with this motto, *Nemo me impune lacessit*.

About the year 1711, several objections being urged against Newton's philosophy, in support of Descartes's notions of a plenum, Keill published a paper in the *Philos. Trans.* on the Rarity of Matter, and the Tenuity of its

Composition. While he was engaged in this dispute, Queen Anne was pleased to appoint him her decipherer; and he continued in that place under King George the 1st till the year 1716. The university of Oxford conferred on him the degree of M. D. in 1713; and two years after, he published an edition of Commandine's *Euclid*, with additions of his own. In 1718 he published his *Introductio ad Veram Astronomiam*; which was afterwards, at the request of the duchess of Chandos, translated by himself into English; and, with several emendations, published in 1721, under the title of *An Introduction to True Astronomy, &c.* This was his last gift to the public; for being that summer seized with a violent fever, it terminated his life Sept. 1, in the 50th year of his age.—His papers in the *Philos. Trans.* above alluded to, are contained in volumes 26 and 29.

KEILL (Dr. *James*), an eminent physician and philosopher, and younger brother of Dr. John Keill above mentioned, was also born in Scotland, in 1673. Having travelled abroad, on his return he read lectures on anatomy with great applause in the universities of Oxford and Cambridge, by the latter of which he had the degree of M. D. conferred upon him. In 1703 he settled at Northampton as a physician, where he died of a cancer in the mouth in 1719. His publications are

1. An English translation of Lemery's Chemistry.
2. On Animal Secretion, the quantity of Blood in the Human Body, and on Muscular Motion.
3. A treatise on Anatomy.
4. Some pieces in the *Philos. Trans.* vols. 25 and 30.

KEPLER (*JOHN*), a very eminent astronomer and mathematician, was born at Wiel, in the duchy of Wirtemberg, in 1571. He was the disciple of Maestlinus, a learned mathematician and astronomer, of whom he learned those sciences, and became afterwards professor of them to three successive emperors, viz., Matthias, Rudolphus, and Ferdinand the 2d.

To this sagacious philosopher we owe the first discovery of the great laws of the planetary motions, viz., that the planets describe areas that are always proportional to the times; that they move in elliptical orbits, having the sun in one focus; and that the squares of their periodic times, are proportional to the cubes of their mean distances; which are now generally known by the name of Kepler's Laws. As this great man stands as it were at the head of the modern astronomers, we shall enter at some length into his history, and chiefly from the words of that celebrated mathematician Mr. Maclaurin.

Kepler had a particular passion for finding analogies and harmonies in nature, after the manner of the Pythagoreans and Platonists; and to this disposition we owe such valuable discoveries, as are more than sufficient to excuse his conceits. Three things, he tells us, he anxiously sought to find out the reason of, from his early youth; viz., Why the planets were 6 in number? Why the dimensions of their orbits were such as Copernicus had described from observations? And what was the analogy or law of their revolutions? He sought for the reasons of the two first of these, in the properties of numbers, and plane figures, without success; but at length reflecting, that while the plane regular figures may be infinite in number, the regular solids are only five, as Euclid had long ago demonstrated; he imagined, that certain mysteries in nature might correspond with this remarkable limitation inherent in the essences of things; and the rather, as he found

that the Pythagoreans had made great use of those five regular solids in their philosophy. He therefore endeavoured to find some relation between the dimensions of these solids and the intervals of the planetary spheres; thus, imagining that a cube, inscribed in the sphere of Saturn, would touch by its six planes the sphere of Jupiter; and that the other four regular solids in like manner fitted the intervals that are between the spheres of the other planets: he at length became persuaded that this was the true reason why the primary planets were precisely six in number, and that the Author of the World had determined their distances from the sun, the centre of the system, from a regard to this analogy. Being thus possessed, as he thought, of the grand secret of the Pythagoreans, and greatly pleased with his discovery, he published it in 1596, under the title of *Mysterium Cosmographicum*: and was for some time so charmed with it, that he said he would not give up the honour of having invented what was contained in that book, for the electorate of Saxony.

Kepler sent a copy of this book to Tycho Brahe, who did not approve of those abstract speculations concerning the system of the world, but wrote to Kepler, first to lay a solid foundation in observations, and then, by ascending from them, to endeavour to come at the causes of things. Tycho, however, pleased with his genius, was very desirous of having Kepler with him to assist him in his labours: and having settled, under the protection of the emperor, in Bohemia, where he passed the last years of his life, after having left his native country on account of some ill usage, he prevailed upon Kepler to leave the university of Gratz, and remove into Bohemia, with his family and library, in the year 1600. But Tycho dying the next year, the task of arranging the observations devolved upon Kepler, and from that time he had the title of Mathematician to the Emperor all his life, and gained continually more and more reputation by his works. The emperor Rudolph ordered him to finish the tables of Tycho Brahe, which were to be called the Rudolphine Tables, &c. Kepler applied diligently to the work: but unhappy are those learned men who depend on the good-humour of the intendants of the finances; the treasurers were so ill-affected towards our author, that he could not publish these tables till 1627. He died at Ratisbon, in 1630, where he was soliciting the payment of the arrears of his pension.

Kepler made many important discoveries from Tycho's observations, as well as from his own. He found, that astronomers had erred, from the first rise of the science, in ascribing always circular orbits and uniform motions to the planets; that, on the contrary, each of them moves in an ellipsis which has one of its foci in the sun: that the motion of each is really unequal, and varies so, that a ray supposed to be always drawn from the planet to the sun describes equal areas in equal times.

It was some years later before he discovered the analogy existing between the distances of the several planets from the sun, and the periods in which they complete their revolutions. He easily saw, that the higher planets not only moved in greater circuits, but also slower than those near the sun; so that, on a double account, their periodic times were greater. Saturn, for example, revolves at the distance from the sun $9\frac{1}{2}$ times greater than the earth's distance from it; and the orbit of Saturn is therefore in the same proportion: but as the earth revolves in one year, so, if their velocities were equal, Saturn ought to re-

volve in 9 years and a half; whereas the periodic time of Saturn is about 29 years. The periodic times of the planets increase, therefore, in a greater proportion than their distances from the sun; but yet not in so great a proportion as the squares of those distances; for if that were the law of the motions, (the square of $9\frac{1}{2}$ being $90\frac{1}{4}$), the periodic time of Saturn ought to be above 90 years. A mean proportion between that of the distances of the planets, and that of the squares of those distances, is the true proportion of the periodic times; as the mean between $9\frac{1}{2}$ and its square $90\frac{1}{4}$, gives the periodic time of Saturn in years. Kepler, after having committed several mistakes in determining this analogy, hit upon it at last, May 15, 1618; for he is so particular as to mention the precise day when he found that "The squares of the periodic times were always in the same proportion as the cubes of their mean distances from the sun."

When Kepler saw, according to better observations, that his disposition of the five regular solids among the planetary spheres, was not agreeable to the intervals between their orbits, he endeavoured to discover other schemes of harmony; for which purpose, he compared the motions of the same planet at its greatest and least distances, and of the different planets in their several orbits, as they would appear viewed from the sun; and here he fancied that he found a similitude to the divisions of the octave in music. These were the dreams of this ingenious man, which he was so fond of, that, hearing of the discovery of four new planets (the satellites of Jupiter) by Galileo, he owns that his first reflections were from a concern how he could save his favourite scheme, which was threatened by this addition to the number of the planets. The same attachment led him into a wrong judgment concerning the sphere of the fixed stars: for being obliged, by his doctrine, to allow a vast superiority to the sun in the universe, he restrains the fixed stars within very narrow limits: nor did he consider them as suns, placed in the centres of their several systems, having planets revolving around them; as the other followers of Copernicus had allowed them to be, from their having light in themselves, from their immense distances, and from the analogy of nature. Not contented with these harmonies, which he had learned from the observations of Tycho, he gave himself the liberty to imagine several other analogies, that have no foundation in nature, and are overthrown by the best observations. Thus from the opinions of Kepler, though most justly admired, we are taught the danger of espousing principles, or hypotheses, borrowed from abstract sciences, and of applying them, with such freedom, to natural enquiries.

A more recent instance of this fondness for discovering analogies between matters of abstract speculation, and the constitution of nature, we find in Huygens, one of the greatest geometers and astronomers any age has produced: when he had discovered that satellite of Saturn, which from him is still called the Huygenian satellite, this, with our moon, and the four satellites of Jupiter, completed the number of six secondary planets then discovered in the system; and because the number of primary planets was also six, and this number is called by mathematicians a perfect number (being equal to the sum of its aliquot parts, 1, 2, 3,) Huygens was hence induced to believe that the number of the planets was complete, and that it was in vain to look for any more. This is not mentioned to lessen the credit of this great man, who

never perhaps reasoned in such a manner on any other occasion; but only to show, by another instance, how ill-grounded reasonings of this kind have always proved. For, not long after, the celebrated Cassini discovered four more satellites about Saturn, not to mention the three others that have been discovered belonging to that planet by Dr. Herschel, with another new primary planet and its 6 satellites, besides the other new planets lately discovered. The same Cassini having found that the analogy, discovered by Kepler, between the periodic times and the distances from the centre, takes place in the lesser systems of Jupiter and Saturn, as well as in the great solar system; his observations overturned that groundless analogy which had been imagined between the number of the planets, both primary and secondary, and the number six: but established, at the same time, that harmony in their motions, which will afterwards appear to flow from one real principle extended throughout the universe.

But to return to Kepler; his great sagacity, and continual meditations on the planetary motions, suggested to him some views of the true principles from which these motions flow. In his preface to the commentaries concerning the planet Mars, he speaks of gravity as of a power that was mutual between bodies, and tells us, that the earth and moon tend towards each other, and would meet in a point, so many times nearer to the earth than to the moon, as the earth is greater than the moon, if their motions did not prevent it. He adds also that the tides arise from the gravity of the waters towards the moon. But not having notions sufficiently just of the laws of motion, it seems he was not able to make the best use of these thoughts; nor does it appear that he adhered to them steadily; since in his Epitome of Astronomy, published many years after, he proposes a physical account of the planetary motions, derived from different principles.

He supposes, in that treatise, that the motion of the sun on his axis, is preserved by some inherent vital principle; that a certain virtue, or immaterial image of the sun, is diffused with his rays into the ambient spaces, and, revolving with the body of the sun on his axis, takes hold of the planets, and carries them along with it in the same direction; like as a loadstone turned round near a magnetic needle, makes it turn round at the same time. The planet, according to him, by its inertia, endeavours to continue in its place, and the action of the sun's image and this inertia are in a perpetual struggle. He adds, that this action of the sun, like his light, decreases as the distance increases; and therefore moves the same planet with greater celerity when nearer the sun, than at a greater distance. To account for the planet's approaching towards the sun as it descends from the aphelion to the perihelion, and receding from the sun while it ascends to the aphelion again, he supposes that the sun attracts one part of each planet, and repels the opposite part; and that the part attracted is turned towards the sun in the descent, and the other towards the sun in the ascent. By suppositions of this kind, he endeavoured to account for all the other varieties of the celestial motions.

But, now that the laws of motion are better known than they were in Kepler's time, it is easy to show the fallacy of every part of this account of the planetary motions. The planet does not endeavour to stop in consequence of its inertia, but to persevere in its motion in a right line. An attractive force makes it descend from the aphelion to the perihelion in a curve concave towards the sun: but

the repelling force, which he supposed to begin at the perihelion, would cause it to ascend in a figure convex towards the sun. There will be occasion to show afterwards from Sir Isaac Newton, how an attraction or gravitation towards the sun, alone produces the effects, which, according to Kepler, required both an attractive and repelling force; and that the virtue which he ascribed to the sun's image, propagated into the planetary regions, is unnecessary, as it could be of no use for this effect, though it were admitted. For now his own prophecy, with which he concludes his book, is verified; where he tells us, that, "the discovery of such things was reserved for the succeeding ages, when the Author of Nature would be pleased to reveal these mysteries."—The works of this celebrated author are many and valuable; as,

1. His Cosmographical Mystery, 1596.
2. Optical Astronomy, in 1604.
3. Account of a New Star in Sagittarius, 1605.
4. New Astronomy; or, Celestial Physics, in Commentaries on the Planet Mars.
5. Dissertations; with the Nuncius Siderius of Galileo, 1610.
6. New Gauging of Wine Casks, 1615. Said to be written on occasion of an erroneous measurement of the wine at his marriage by the revenue officer.
7. New Ephemerides, from 1617 to 1620.
8. Copernican System, three first books of the, 1618.
9. Harmony of the World; and 3 books of Comets, 1619.
10. Cosmographical Mystery, 2d edit. with Notes, 1621.
11. Copernican Astronomy; the last 3 books, 1622.
12. Logarithms, 1624; and the Supplement, in 1625.
13. His Astronomical Tables, called the Rudolphine Tables, in honour of the emperor Rudolphus, his great and learned patron, in 1627.
14. Epitome of the Copernican Astronomy, 1635.

Besides these, he wrote several pieces on various other branches, as Chronology, Geometry of Solids, Trigonometry, and an excellent treatise of Dioptrics, for that time. His numerous manuscripts were purchased from his representatives, by Hevelius, and were probably consumed by a fire at the observatory of the latter, in the year 1679, which destroyed many of his valuable books and instruments.

K E P L E R'S LAWS, are those laws of the planetary motions discovered by Kepler. These discoveries in the mundane system, are commonly accounted two, viz. 1st, That the planets describe about the sun, areas that are proportional to the times in which they are described, namely, by a line connecting the sun and planet; and 2d, That the squares of the times of revolution, are as the cubes of the mean distances of the planets from the sun. Kepler discovered also that the orbits of the planets are elliptical.

These discoveries of Kepler, however, were only found out by many trials, in searching among a great number of astronomical observations and revolutions, what rules and laws were found to obtain. On the other hand, Newton has demonstrated, *a priori*, all these laws, showing that they *must* obtain in the mundane system, from the laws of gravitation and centripetal force; viz, the first of these laws resulting from a centripetal force urging the planets towards the sun, and the 2d, from the centripetal force being in an inverse ratio of the square of the distance. And the elliptic form of the orbits, from a projectile force regulated by a centripetal one.

KEPLER'S Problem, is the determining the true from the mean anomaly of a planet, or the determining its place, in its elliptic orbit, answering to any given time; and so named from the celebrated astronomer Kepler, who first proposed it. See ANOMALY.

The general state of the problem is this: To find the position of a right line, which, passing through one of the foci of an ellipsis, shall cut off an area which shall be in any given proportion to the whole area of the ellipsis; which results from this property, that such a line sweeps areas that are proportional to the times. Many solutions have been given of this problem, some direct and geometrical, others not; viz. by Kepler, Bulliald, Ward, Newton, Keill, Machin, &c. See Newton's Princip. lib. 1. prop. 31, Keill's Astron. Lect. 23, Philos. Trans. Abr. vol. 8, pa. 177, &c.

In the last of these places, Mr. Machin observes, that many attempts have been made at different times, but with no great success, towards the solution of the problem proposed by Kepler: To divide the area of a semicircle into given parts, by a line drawn from a given point in the diameter, in order to find a universal rule for the motion of a body in an elliptic orbit. For, among the several methods offered, some are only true in speculation, but are really of no service; others are not different from his own, which he judged improper. And as to the rest, they are all so limited and confined to particular conditions and circumstances, as still to leave the problem in general untouched. To be more particular; it is evident, that all constructions by mechanical curves are seeming solutions only, being in reality unapplicable; that the roots of infinite series are, on account of their known limitations in all respects, so far from being sufficient rules, that they serve for little more than exercises in a method of calculation. And then, as to the universal method, which proceeds by a continued correction of the errors of a false position, it is no method of solution at all in itself; because, unless there be some antecedent rule or hypothesis to begin the operation (as suppose that of an uniform motion about the upper focus, for the orbit of a planet; or that of a motion in a parabola for the perihelion part of the orbit of a comet, or something of a similar nature,) it would be impossible to proceed one step in it. But as no general rule has ever yet been laid down, to assist this method, so as to make it always operate, it is the same in effect as if there were no method at all. And accordingly in experience it is found, that there is no rule now subsisting but what is absolutely useless in the elliptic orbits of comets; for in such cases there is no other way to proceed but that which was used by Kepler: to compute a table for some part of the orbit, and in it examine if the time to which the place is required, will fall out anywhere in that part. So that, upon the whole, it appears evident, that this problem, contrary to the received opinion, has never yet been advanced one step towards its true solution.

Mr. Machin then proceeds to give his own solution of this problem, which is particularly necessary in orbits of a great eccentricity; and he illustrates his method by examples for the orbits of Venus, of Mercury, of the comet of the year 1682, and of the great comet of the year 1680, sufficiently showing the universality of the method.

KEY, in Music, is a certain fundamental note, or tone, to which the whole piece, be it concerto, sonata, cantata, &c, is accommodated; and with which it usually begins, and always ends.—See CLEF.

KEYES denote also, in an organ, or harpsichord, &c, the pieces of wood or ivory which are struck by the fingers, in playing upon the instrument.

KEYSTONE, is the middle voussoir, or the arch stone in the top, or immediately over the centre of an arch.—The length of the keystone, or thickness of the archivolt at top, is allowed by the best architects, to be about the 15th or 16th part of the span.

KILDERKIN, a kind of liquid measure, containing two firkins, or 18 gallons, beer-measure.

KING-piece, or **KING-post**, is a piece of timber set upright in the middle, between two principal rafters, and having struts or braces going from it to the middle of each rafter.

KIRBY (*Josua*), was the eldest of the five sons of Mr. John Kirby; who was originally a schoolmaster at Oxford; but afterwards took an actual survey of the county of Suffolk in the year 1732, &c, and published a small map of it; as also the Suffolk Traveller, 1735, 12mo; a new and enlarged edition of which was published by subscription in 1764, in which the name of "Joshua Kirby, Esq. designer in perspective to his majesty," occurs for 50 copies. Mr. John Kirby died at Ipswich, Dec. 13, 1753, aged 63.

Our author Joshua was born in 1716, at Parham, near Wickham-Market; and settled as a house-painter at Ipswich about the year 1738. He always had a genius for drawing, and published 12 prints of castles, ancient churches and monuments, in Suffolk, with a small pamphlet, containing further illustrations of them. But the study which led him to eminence, was that of the art of perspective, in his improvement of which it may almost be said that he invented a new art; so simple was his method, in comparison with the systems at that time in use. He had made a considerable progress in his treatise, when he met with Dr. Brook Taylor's book, which contributed to the perfecting of those rules, by which he rendered this art so easy, that on the publication of his work he was requested by the Society of Artists to read lectures; for which he received the thanks of its members, in the public papers.

Having obtained the friendship and intimacy of Sir Joshua Reynolds, Mr. Hogarth, and other eminent artists, he quitted Ipswich, and removed to London; where he was patronized by the earl of Bute, who introduced him to his present majesty, when prince of Wales, and was appointed clerk of the works at Kew. By his majesty's patronage he published, in 1761, his splendid work, *The Perspective of Architecture*, in 2 vols. folio; being a masterly performance, and the elegant designs with which it is illustrated reflect honour on the artists of our country.—In 1766, in conjunction with his brother William, then of Witnesham, in the county of Suffolk, attorney at law (who died Sept. 25, 1791, aged 72), he published an improved edition of their father's map of Suffolk, on a larger scale. Mr. K. was a member both of the Royal and Antiquarian Societies; and, at the first forming of the Royal Academy, he was president of the Society for Artists, from which that institution emanated. In the year 1768 he published a 3d edition of his Treatise on Perspective. Mr. K. died June 20, 1774, aged 58, and was buried in Kew churchyard, leaving his widow, who died the year after, and a daughter, the celebrated Mrs. Trimmer, of Old Brentford, esteemed for numerous works for the instruction of youth.

KIRCH (*CHRISTIAN FREDERIC*), of Berlin, a cele-

bated astronomer, was born at Guben in 1694. He acquired great reputation in the observatories of Dantzig and Berlin. Godfrey Kirch his father, and Mary his mother, also acquired considerable reputation by their astronomical observations. This family corresponded with all the learned societies of Europe, and their astronomical works are in great repute.

KIRCHER (ATHANASIUS), a noted philosopher and mathematician, was born at Fulde in 1601. He entered into the society of the Jesuits in 1618, and taught philosophy, mathematics, the Hebrew and Syriac languages, in the university of Wirsburg, with great applause, till the year 1631; when he retired to France, on account of the ravages committed by the Swedes in Franconia, and lived some time at Avignon. He was afterwards called to Rome, where he taught mathematics in the Roman college, collected a rich cabinet of machines and antiquities, and died in 1680, in the 80th year of his age.

The quantity of his works is immense, amounting to 22 volumes in folio, 11 in quarto, and three in octavo; enough to employ a man for a great part of his life even to transcribe them. Most of them are rather curious than useful; many of them visionary and fanciful; and it is not to be wondered at if they are not always accompanied with the greatest exactness and precision. The principal of them are,

1. *Prælusiones Magneticæ.*
2. *Primitiæ Gnomonice Catoptricæ.*
3. *Ars magna Lucis et Umbrae.*
4. *Musurgia Universalis.*
5. *Obeliscus Pamphilii.*
6. *Oedipus Ægyptiacus;* 4 volumes folio.
7. *Itinerarium Extaticum.*
8. *Obeliscus Ægyptiacus;* 4 volumes folio.
9. *Mundus Subterraneus.*
10. *China Illustrata.*

KNOT, a tye, or complication of a rope, cord, or string, or of the ends of two together. There are divers sorts of knots used for different purposes, which may be explained by shewing the figures of them open, or undrawn, thus. 1. Fig. 1, plate 17, is a *Thumb knot*. This is the simplest of all. It is used to tye at the end of a rope, to prevent its opening out: it is also used by taylors, &c, at the end of their thread.

Fig. 2, a *Loop knot*. Used to join pieces of rope, &c, together.—Fig. 3, a *Draw knot*, which is the same as the last; only one end or both return the same way back, as *a b c d*. By drawing at *a*, the part *b c d* comes through, and the knot is loosed.—Fig. 4, a *Ring knot*. This serves also to join pieces of cord, &c, together.—Fig. 5 is another knot for tying cords together. This is used when any cord is often to be loosed.—Fig. 6, a *Running knot*, to draw any thing close. By pulling at the end *a*, the cord is drawn

through the loop *b*, and the part *c d* is drawn close about a beam, &c.—Fig. 7 is another knot, to tie any thing to a post. And here the end may be put through as often as you please.—Fig. 8, a *Very small knot*. A thumb knot is first made at the end of each piece, and then the end of the other is passed through it. Thus, the cord *a c* runs through the loop *d*, and *b d* through *c*; and then drawn close by pulling at *a* and *b*. If the ends *e* and *f* be drawn, the knot will be loosed again.—Fig. 9, a *Fisher's knot*, or *Water knot*. This is the same as the 4th, only the ends are to be put twice through the ring, which in the former was but once; and then drawn close.—Fig. 10, a *Meshing knot*, for nets; and is to be drawn close.—Fig. 11, a *Barber's knot*, or a knot for cawls of wigs; and is to be drawn close.—Fig. 12, a *Bouline knot*. When this is drawn close, it makes a loop that will not slip, as fig. 7; and serves to hitch over any thing.—Fig. 13, a *Wale knot*, which is made with the three strands of a rope, so that it cannot slip. When the rope is put through a hole, this knot keeps it from slipping through. When the three strands are wrought round once or twice more, after the same manner, it is called *crowning*. By this means the knot is made larger and stronger. A thumb knot, No. 1, may be applied to the same use as this.

KNOTS mean also the divisions of the log line, used at sea. These are usually 7 fathoms, or 42 feet asunder; but should be $8\frac{1}{2}$ fathoms, or 50 feet. And then, as many knots as the log line runs out in half a minute, so many miles does the ship sail in an hour; supposing her to keep going at an equal rate, and allowing for yaws, leeway, &c.

KOENIG (SAMUEL), a learned philosopher and mathematician, was a Swiss by birth, and came early into eminence by his mathematical abilities. He was professor of philosophy and natural law at Fratcker, and afterwards at the Hague, where he became also librarian to the stadholder, and to the princess of Orange; and where he died in 1757.

The Academy of Berlin enrolled him among her members; but afterwards expelled him on the following occasion. Maupertuis, the president, had inserted in the volume of the Memoirs for 1746, a discourse on the Laws of Motion; which Koenig not only attacked, but also attributed the memoir to Leibnitz. Maupertuis, stung with the imputation of plagiarism, engaged the Academy of Berlin to call upon him for his proof; which Koenig failing to produce, he was struck out of the academy. All Europe was interested in the quarrel which this occasioned between Koenig and Maupertuis. The former appealed to the public; and his appeal, written with the animation of resentment, procured him many friends. He was author of some other works, and had the character of being one of the best mathematicians of the age.

L.

LABEL, a long thin brass ruler, with a small sight at one end, and a central hole at the other; commonly used with a tangent-line on the edge of a circumferentor, to take altitudes, and other angles.

LACAILLE (NICHOLAS LEWIS), an eminent French mathematician and astronomer, was born at Rumiugy in the diocese of Rheims, in 1713. His father having quitted the army, in which he had served, amused himself in his retirement with studying mathematics and mechanics, in which he proved the happy author of several inventions of considerable use to the public. From this example of his father, our author almost in his infancy took a fancy to mechanics, and at school discovered very early tokens of genius. In 1729 he came to Paris, where he studied the classics, philosophy, and mathematics. He afterwards studied divinity in the college de Navarre, with the view of embracing the ecclesiastical life: however he never entered into priest's orders, apprehending that his astronomical studies, to which he had become much devoted, might too much interfere with his religious duties. His attachment to astronomy soon connected him with the celebrated Cassini, who procured him an apartment in the observatory; where, assisted by the counsels of this celebrated man, he soon acquired a name among the astronomers. In 1739 he was engaged with M. Cassini de Thury, son to M. Cassini, in verifying the meridian through the whole extent of France: and in the same year he was named professor of mathematics in the college of Mazarine. In 1741 our author was admitted into the Academy of Sciences as an adjoint member for astronomy; and had many excellent papers inserted in their Memoirs; beside which he published several useful treatises, *viz.* Elements of Geometry, Astronomy, Mechanics, and Optics. He also carefully computed all the eclipses of the sun and moon that had happened since the Christian æra, which were printed in the work entitled *l'Art de verifier les Dates, &c.*, Paris 1750, in 4to. He also compiled a volume of astronomical ephemerides for the years 1745 to 1755; another for the years 1755 to 1765; and a third for the years 1765 to 1775: as also the most correct solar tables of any; and an excellent work entitled *Astronomiae fundamenta novissimis solis et stellarum observationibus stabilita*.

Having gone through a series of seven years' astronomical observations in his own observatory in the Mazarine college, he formed the project of going to observe the southern stars at the Cape of Good Hope: being countenanced by the French court, he set out upon this expedition in 1750, and in two years he observed the places of about 10 thousand stars in the southern hemisphere that are not visible in our latitudes, as well as many other important elements, *viz.* the parallaxes of the sun, moon, and some of the planets, the obliquity of the ecliptic, the refractions, &c. Having thus executed the purpose of his voyage, and no present opportunity offering for his return, he thought of employing the vacant time in another arduous attempt, namely that of taking the measure of the earth, as he had already done that of the heavens. This indeed had been done before by many learned men both in Europe and America; some determining the quantity of

VOL. I.

a degree at the equator, and others at the arctic circle; but it had not yet been decided whether in the southern parallels of latitude the same dimensions obtained as in the northern. His labours were rewarded with the satisfaction he wished for; having determined a distance of 410814 feet from a place called Klip-Fontyn to the Cape, by means of a base of 38802 feet, three times actually measured: he discovered a new secret of nature, namely, that the radii of the parallels in south latitude are not of the same length as those of the corresponding parallels in north latitude. About the 23d degree of south latitude he found a degree on the meridian to contain 342222 Paris feet. Agreeably to the orders from the court of Versailles, he fixed the situation of the Isles of France and of Bourbon. While at the Cape, he observed a wonderful effect of the atmosphere in some states of it: though the sky at the Cape be generally pure and serene, yet when the south-east wind blows, which is pretty often, it is attended with some strange and even terrible effects: the stars look larger, and appear to dance; the moon has an undulating tremor; and the planets have a sort of beard like comets.

M. Lacaillé returned to France in the autumn of 1754, after an absence of 4 years; loaded, not with the spoils of the east, but with those of the southern heavens, before then almost unknown to astronomers. On his return, he first drew up a reply to some strictures which the celebrated Euler had published relative to the meridian: after which he settled the results of the comparison of his observations for the parallaxes, with those of other astronomers: that of the sun he fixed at 93"; of the moon at 56' 56"; of Mars in his opposition, 36"; of Venus 38". He also settled the laws by which astronomical refractions are varied by the different density or rarity of the air, by heat or cold, and by dryness or moisture. And lastly he showed an easy and practicable method of finding the longitude at sea by means of the moon. His fame being now generally established, he was elected a member of most of the academies and societies of Europe, as London, Bologna, Petersburg, Berlin, Stockholm, and Göttingen.

In 1760 our author was attacked with a severe fit of the gout; which however did not interrupt the course of his studies; for he then planned a new and large work, intended as a history of astronomy through all ages, with a comparison of the ancient and modern observations, and the construction and use of the instruments employed in making them. Towards the latter part of 1761, his constitution became greatly reduced; though his mind continued unaffected, and he resolutely persisted in his studies to the last; death only putting an end to his labours the 21st of March 1762, at 49 years of age; after having committed his manuscripts to the care and discretion of his esteemed friend M. Maraldi.

Besides the publications before mentioned, and perhaps some others also, he had a vast number of papers inserted in the volumes of the Memoirs of the French Academy of Sciences, much too numerous indeed, though very important, to be here all mentioned particularly; suffice it therefore just to distinguish the years of those volumes in

which his pieces are to be found, by the following list of them, viz, 1741, 1742, 1743, 1744, 1745, 1746, 1747, 1748, 1749, 1750, 1751, 1752, 1753, 1754, 1755, 1756, 1757, 1758, 1759, 1760, 1761, 1763; in all or most of which years there are two or three or more of his papers.

LACERTA, *Lizard*, one of the new constellations of the northern hemisphere, added by Hevelius to the 48 old ones, near Cepheus and Cassiopeia. This constellation contains, in Hevelius's catalogue 10 stars, and in Flamsteed's 16.

LACUNAR, an arched roof or ceiling; more especially the planking or flooring above the porticos.

LADY-DAY, the 25th of March, being the Annunciation of the Holy Virgin.

LAGNY (*THOMAS FANTET DE*), an eminent French mathematician, was born at Lyons. Fournier's Euclid, and Pelletier's Algebra, by chance falling in his way, developed his genius for the mathematics. It was in vain that his father designed him for the law; he went to Paris to deliver himself wholly up to the study of his favourite science; and in 1697, the Abbé Bignon, protector-general of letters, got him appointed professor-royal of hydrography at Rochefort. Soon after, the duke of Orleans, then regent of France, fixed him at Paris, and made him sub-director of the general bank, in which he lost the greatest part of his fortune in the failure of that establishment. He had been received into the ancient academy in 1696; on the renewal of which he was named associate-geometrician in 1699, and pensioner in 1723. After a life spent in close application, he died, April 12, 1734.

De Lagny particularly excelled in arithmetic, algebra, and geometry, in which he made many improvements and discoveries. He, as well as Leibnitz, invented a binary arithmetic, in which only two figures are concerned. He rendered much easier the resolution of algebraic equations, especially the irreducible case in cubic equations; and the numerical resolution of the higher powers, by means of short approximating theorems.—He delivered the measures of angles in a new science, called Goniometry; in which he measured angles by a pair of compasses, without scales, or tables, to great exactness; and thus gave a new appearance to trigonometry.—Cyclometry, or the measure of the circle, was also an object of his attention; and he calculated, by means of infinite series, the ratio of the circumference of a circle to its diameter, to 120 places of figures.—He gave a general theorem for the tangents of multiple arcs: with many other curious or useful improvements, which are found in the great multitude of his papers, that are printed in the different volumes of the Memoirs of the Academy of Sciences, viz, in almost every volume, from the year 1699 to 1729.

LAGRANGE (*JOSEPH LOUIS*), a most illustrious mathematician and philosopher, was born at Turin, Nov. 25, 1736, and died at Paris, April 1813. His father was treasurer of war; but falling into poverty through unfortunate speculations, induced our author to endeavour to render himself distinguished in literature. His taste however for mathematics did not appear early. He was passionately devoted to Cicero and Virgil, before he could relish Archimedes and Newton. He soon however became an enthusiastic admirer of the geometry of the ancients, which he at first preferred to the modern analysis. But a memoir which the celebrated Halley had composed

to demonstrate the superiority of the analytic method, had the effect of teaching him his true path to glory. He devoted himself to this new study with the same success that he had had to synthesis; and his application was so decided, that at the age of 16, he became professor of mathematics in the royal military school at Turin.

The youth of the professor however had no effect in hindering the pupils, all older than himself, from profiting, by his lessons. Some of them he distinguished as his friends; and this early association laid the foundation of an important institution, the Academy of Turin, which published, in 1759, a first volume, under the title of *Actes de la Société Privée*. In those acts it appears that the young Lagrange directed the philosophical researches of Cigna the anatomist, and the labours of the Chevalier de Saluces. He furnished to Foncenex the analytical part of his memoirs, leaving to him the task of developing the reasoning upon which the formulas depended. But Lagrange, while he abandoned insulated theorems, published at the same time, under his own name, theories which he promised to develop further. Thus, after giving new formulas of maxima and minima, in all cases, after having shown the insufficiency of the known methods, he announced that he would treat this subject, which he considered as important, in a work which he was preparing, in which would be deduced, from the same principles, all the mechanical properties of bodies, whether solid or fluid, thereby laying, at the age of 23, the foundation of those great works which constitute the admiration of philosophers.

Newton had undertaken to submit the motions of fluids to calculation, and had made researches on the propagation of sound; but his principles were insufficient, and his suppositions sometimes erroneous. Lagrange demonstrated this, and founded his researches on the known laws of dynamics, by considering only in the air the particles which are in a straight line, thereby reducing the problem to that of vibrating chords. He demonstrated, that, whatever figure is given to the chord, the duration of the oscillations is always the same: a truth derived from experiment, but which Dalembert considered as very difficult, if not impossible, to demonstrate. He then passed to the propagation of sound, treated of simple and compound echoes, of the mixture of sounds, of the possibility of their spreading in the same space without interfering with each other, and demonstrated rigorously the generation of harmonious sounds.

Euler saw the merit of the new method, and adopted it as an object of his profoundest meditations; but Dalembert did not yield the point in dispute. In his private letters, as well as in his printed memoirs, he proposed numerous objections, to which Lagrange afterwards answered. The first notice of Euler was to make Lagrange an associate of the Berlin academy. When he announced to him this nomination on the 20th of October, 1759, he said, "Your solution of the problem of isoperimeters leaves nothing to desire; and I am happy that this subject, with which I have been almost solely occupied since my first attempts, has been carried by you to the highest degree of perfection. The importance of the point has induced me to draw up, with your assistance, an analytical solution of it. But I shall not publish it till you have published the sequel of your researches, that I may not deprive you of any part of the glory which is your due."

Dalembert considered it impossible to subject to calculation the motions of a fluid inclosed in a vessel, unless

this vessel had a certain figure. Lagrange demonstrated the contrary; except in the case when the fluid divides itself into different masses. But even then we may determine the places where the fluid divides itself into different portions, and determine the motion of each as if it were alone. Dalembert thought, that in a fluid mass, such as the earth may have been at its origin, it was not necessary for the different beds to be on a level; but Lagrange shows, that the equations of Dalembert are themselves equations of beds on a level. In combating Dalembert with all the respect due to a mathematician of his rank, he often employed very beautiful theorems, for which he had been indebted to his adversary. Dalembert, on his side, added to the delicacy of Lagrange. "Your problem appeared to me so beautiful," says he in a letter to Lagrange, "that I have sought for another solution of it. I have found a simpler method of arriving at your elegant formula."

The Academy of Sciences of Paris proposed, at this time (1764), as the subject of a prize, the theory of the libration of the moon, i. e. they demanded the cause why the moon, in revolving round the earth, always turns the same face to it, some variations excepted, observed by astronomers, and of which Cassini had first explained the phenomenon. The point was to calculate all the phenomena, and to deduce them from the principle of universal gravitation. Such a subject was an appeal to the genius of Lagrange, an opportunity furnished to apply his analytical principles and discoveries. The hope of Dalembert was not disappointed, and the memoir of Lagrange is one of his finest pieces. We see in it the germ of his *Mecanique Analytique*. Dalembert wrote to him: "I have read with as much pleasure as advantage, your excellent paper on the moon's librations, so worthy of the prize which it has obtained."

This success encouraged the Academy to propose, as a prize, the theory of the satellites of Jupiter. Euler, Clairaut, and Dalembert, employed themselves about the problem of these bodies on the principle of the movements of the moon. Baily applied the theory of Clairaut to the problem of the satellites, and it led him to some interesting results. But his theory was insufficient; the earth has only one moon, while Jupiter has four, which continue to act upon each other, and vary their positions in their revolutions. The problem was one of six bodies: but Lagrange attacked the difficulty and overcame it, demonstrating the cause of the inequalities observed by astronomers, and pointing out some others too trivial to be ascertained by observations. The shortness of the time allowed, and the multiplicity of the calculations, analytical and numerical, did not permit him to exhaust the subject entirely in a first memoir. He was sensible of this himself, and promised further results, which his other labours always prevented him from completing; but twenty-four years after, M. Laplace took up that difficult theory, and completed it.

About the same time a problem of a different kind drew the attention of M. Lagrange. Fermat, a great mathematician, had left some remarkable theorems respecting the properties of numbers, which it seems he discovered by induction. He promised the demonstrations of them, but at his death no trace of them could be found. Many mathematicians employed themselves on the theorems of Fermat; but none were successful. Euler alone had penetrated into that difficult path; but Lagrange, in demonstrating or rectifying some opinions of Euler, resolved a

problem which gave him a key to all the others; and from which he deduced the complete solution of equations of the second degree, with two indeterminates which must be whole numbers.

His residence at Turin was not agreeable to him. He saw no person who cultivated the mathematics with success. He was impatient to visit Paris. M. de Caraccioli, with whom he lived in the greatest intimacy, was appointed ambassador to London, and was to pass through Paris on his way, where he intended to spend some time. He proposed this journey to M. Lagrange, who accepted it with joy, and was received at Paris, as he had a right to expect, by Dalembert, Clairaut, Condorcet, Fontaine, Nollet, Marie, and the other mathematicians. Falling dangerously ill after a dinner, in the Italian style, given by Nollet, he was not able to accompany his friend to London, who was obliged to leave him in a furnished lodging under the care of an agent.

This incident changed his projects, and he thought of returning to Turin, when he understood that the academy of Berlin was threatened with the loss of Euler, who intended to return to Petersburg. Dalembert suggested the idea of putting Lagrange in the place of Euler, and Euler himself pointed out Lagrange as the only man capable of filling his place. Lagrange was therefore appointed, and he received a pension of 1500 Prussian crowns, about 250*l.*, with the title of director of the academy in regard to the physico-mathematical sciences. Euler and Lagrange, in the place of Maupertuis, received only half his salary, but Frederick had no respect for the sciences, though he considered himself obliged to protect them as a king.

Lagrange took possession of his new situation in 1766. He was well received by the king; but he soon perceived that the Germans do not like foreigners to occupy situations in their country. He applied to the study of their language, and devoted himself to mathematics. "The king," said he, "treated me well; I thought that he preferred me to Euler, who was something of a devotee, while I took no part in the disputes about worship; and did not contradict the opinion of any one."

It will not be expected that I should follow Lagrange in the important researches with which he filled the Berlin Memoirs; and even some volumes of the Memoirs of the Turin Academy, which was indebted to him for its existence. All the space that could be devoted to this biography, would be insufficient to give even an imperfect idea of his labours. Some of these memoirs are of such extent and importance, that they might pass for great separate works, yet they constituted a part only of what those 20 years enabled him to produce. He now composed his *Mecanique Analytique*, and he was anxious to have it printed at Paris; but he experienced great difficulty in finding a bookseller who would undertake to publish a work which, the more sublime the theory, the fewer readers would be found capable of appreciating. At length one was found, and the work was ably edited by M. Legendre, who was repaid by the esteem and the gratitude of the author. The death of Frederick occasioned great changes in Prussia, and still greater were to be apprehended. Philosophers were no longer respected as heretofore, and these causes, with the approaching publication of the *Mecanique Analytique*, were sufficient to bring him back to Paris.

The successor of Frederick, though he did not much

interest himself in the sciences, made some difficulty in allowing a philosopher to depart, whom his predecessor had invited, and whom he had honoured with his particular esteem. After some delay, M. Lagrange obtained liberty to depart, but it was stipulated that he should still give some memoirs to the Berlin academy, and the volumes of 1792, 1793, and 1803, show that he kept his promise.

In 1787 then, Lagrange returned to Paris, to take his seat in the Academy of Sciences, of which he had been a foreign member for 15 years. To give him the right of voting in all their deliberations, this title was changed into that of Veteran Pensionary. The queen treated him with regard, and considered him as a German. He had been recommended to her from Vienna; and he obtained, in consequence, a lodging in the Louvre, where he lived happy till the revolution.

The satisfaction he enjoyed in his new residence, did not however appear outwardly. He was affable and kind when interrogated, but he spoke little, and appeared absent and melancholy. In companies which must have been suited to his taste, among the most distinguished men of all countries who met at the house of the illustrious Lavoisier, he was seen musing, with his head reclined against a window, where nothing seemed to attract his attention. He acknowledged, himself, that his enthusiasm was gone, that he had lost even his taste for mathematics. When informed that any mathematician was employed on a particular object, "so much the better," he would say, "I had begun it, it will now be unnecessary for me to finish it." But he had merely changed the object of his studies. Metaphysics, the history of human nature, of different religions, the general theory of languages, medicine, and botany, divided his leisure hours. Surrounded by chemists who were reforming the theory and language of the science, he made himself acquainted with their discoveries, which gave to facts formerly isolated, that connexion which distinguishes the different parts of mathematics. In this philosophical repose he passed his time till the revolution, without adding any thing to his mathematical discoveries.

The revolution gave philosophers the power of making a great and difficult innovation in the establishment of a system of weights and measures, founded on nature, and perfectly analogous to the decimal scale of numbers. Lagrange was one of the commissioners whom the Academy charged with the execution of that task, and he was one of its most ardent promoters, for he wished to see the decimal system adopted in all its simplicity.

When the academy was suppressed, the commission charged with the establishment of the new system was interrupted for a time. In order to purify it, the names of Lavoisier, Borda, Laplace, Coulomb, Brisson, and Delambre, were struck out. Lagrange was retained, as president; though he could not help expressing his regret at the dismission of so many of his associates; but unless the suppression had been total, it could scarcely have extended to him. Besides, he was known to be wholly devoted to the sciences; he had no place either in the civil department or the administration; and the moderation of his character had prevented him from expressing what he could not but think in secret. The horrors, however, attending the revolution, made a strong impression on his sensible mind. In a conversation with M. Delambre, the day after the atrocious and absurd sentence which, con-

trary to every thing like justice, had thrown all lovers of the sciences into mourning, by cutting off the most illustrious philosopher in Europe, Lavoisier: "It has cost them but a moment," said he, "to cut off that head; but a hundred years perhaps will not be sufficient to produce another like it." Some months before they had had a similar conversation in the cabinet of Lavoisier, on account of the death of the unfortunate Baily. He lamented the dreadful consequences of the dangerous experiment which the French had attempted. The projection of their plans of amelioration appeared to him no certain proofs of greatness in the human mind: "If you wish to see it truly great," added he, "enter into the cabinet of Newton, employed in decomposing light, or in explaining the system of the universe."

For some time he regretted that he had not listened to the advice of his friends, who at the commencement of the troubles had recommended him to seek an asylum, which it would have been so easy to find. As long as the revolution seemed only to threaten the pension which he enjoyed in France, he had neglected that consideration, from a feeling of curiosity to be upon the spot of one of those great convulsions which it is always more prudent to observe at a distance. "It was your own choice," said he several times to himself. It was to no purpose that a special decree of the Constituent Assembly had ensured the payment of his pension, because the depreciation of the paper currency rendered it illusory. He had been named member of the board of consultation, appointed to examine and reward useful inventions, and he had been appointed one of the administrators of the Mint. This commission offered him few objects to fix his attention, and in no degree removed his apprehensions. It was again proposed to draw him to Berlin, and to restore him to his former situation, and he agreed to the proposal. Herault de Sechelles, to whom he applied for a passport, offered him, for greater security, a mission to Prussia; but Madame Lagrange, his wife, would not consent to quit her country; a repugnance which at that time he considered as a misfortune, though it proved a source of fortune and new glory.

The Norman school, of which he was named professor, but which had only an ephemeral existence, scarcely gave him time to explain his ideas respecting the foundation of arithmetic and algebra, and their application to geometry. The Polytechnic school, a happier idea, had a more durable success: and, among the best effects which it produced, we may place that of having restored Lagrange to analysis. There he had an opportunity of developing those ideas, the germ of which was to be found in two memoirs published in 1772, and the object of which was to explain the true metaphysics of the differential and integral calculus. He composed his Analytical Functions, and his Lectures on that Calculus, of which he published several editions. He likewise published his Treatise on the Numerical Solution of Equations, with notes on several points of the theory of algebraic equations.

The desire of multiplying useful applications induced him to undertake a new edition of the *Mecanique Analytique*. His project was to develope the most useful parts of it. He laboured on it with all the ardour and intellectual power which he could have applied at any period of his life. But this application occasioned a degree of fatigue which threw him into a fainting fit, and he was found in that state by Madame Lagrange. His head in

falling had struck against the corner of a table, and the shock had not restored him to his senses. This was a warning to take more care of himself, and he thought so at first; but he was too anxious to finish his work, the printing of which was not completed at the period of his decease. The first volume had appeared some time before his death. It had been followed by a new edition of his *Fonctions Analytiques*. So much labour exhausted him. Towards the end of March (1813) a fever came on, he lost his appetite, his sleep was uneasy, and his waking was accompanied by alarming swoonings. He perceived his danger; but, preserving his serenity, he studied what passed within him, and, as if he were assisting at a great and uncommon experiment, he bestowed all his attention on it. Friendship conducted him to his house, on the 8th of April, MM. Lapepede, Monge, and Chaptal, who wrote down the principal points of a conversation which was his last; and the following passages, within inverted commas, are copied from the manuscript of M. Chaptal.

"He received them with tenderness and cordiality. I was very ill, my friends (said he), the day before yesterday; I perceived myself dying, my body became weaker, my mental and physical powers were gradually declining; I observed with pleasure the gradual diminution of my strength; and I arrived at the point without pain, without regret, and by a very gentle declivity. Death is not to be feared, and when it comes without violence, it is a last function which is neither painful nor disagreeable." He then explained to them his ideas respecting life, the seat of which he considered as spread over the whole body, in every organ, and all parts of the machine, which in his case became equally feebler in every part by the same degree. "A little longer, and there would have been no functions, death would have overspread the whole body, for death is merely the absolute repose of the body; I wished to die," added he with greater force, "I found a pleasure in it; but my wife did not wish it. I should have preferred at that time a wife less kind, less eager to restore my strength, and who would have allowed me gently to have finished my career. I have performed my task, I have acquired some celebrity in the mathematics, I have hated nobody, I have done no ill; it is now proper to finish."

As he exerted himself too much, especially in these last words, his friends, notwithstanding the interest with which they had listened to him, proposed to retire; but he retained them, and began to relate to them the history of his life, his labours, his success, his residence at Berlin, (where he had often told us what he had seen near a king,) of his arrival at Paris, the tranquillity he had enjoyed at first, the anxiety which he suffered during the revolution, and how he had been finally rewarded by a powerful monarch, capable of appreciating his worth, who had loaded him with honours and dignities, and who had even lately sent him the grand ribbon of the Imperial Order of Re-Union. And, it may be added, who, after having given him during his life the most unequivocal proofs of the highest esteem, has since, says M. Delambre, done more for his widow and his brother, than Frederick had done for him all the time he was director of his academy.

He had been ambitious neither of riches nor honour; but he had received both with respectful gratitude, and he rejoiced at the acquisition for the glory of the sciences. He had not lost all hope of cure; he believed only that his convalescence would be long. He offered, when he recov-

ered his strength, to go and dine at M. Lapepede's country-house, with MM. Monge and Chaptal, and proposed to give them details respecting his life, which could no where else be found. During this conversation, which lasted more than two hours, his memory often failed him; he made vain efforts to recover names and dates, but his discourse was always connected, full of strong thoughts and bold expressions. This exercise of his faculties wasted the whole remains of his strength. Scarcely had his friends left him, when he fell into a fainting fit, and he died two days after, on the 10th of April, 1813.

Lagrange was of a delicate but good constitution. His tranquillity, his moderation, and an austere and frugal regimen, from which he rarely deviated, prolonged his life to the age of 76 years, 4 months, and 15 days. He was twice married: first at Berlin, for the purpose of being on a footing with the rest of the academicians, none of whom were bachelors. He afterwards married, in France, Mademoiselle Lemonnier, daughter of the celebrated astronomer of that name. The countess Lagrange, daughter, grand-daughter, and niece, of members of the Academy of Sciences, was deserving of the name which he gave her. This advantage, in her eyes, made up for the difference of their ages, and she soon felt for him the tenderest regard. He was so grateful that he could scarcely bear to be separated from her, and it was on her account alone that he felt any regret at relinquishing life.

Though he had a venerable figure, indicating his excellent characteristics, he would never allow his portrait to be drawn. More than once, by a very excusable piece of address, persons have been introduced during the meeting of the Institute to take a sketch of him without his knowledge.—Gentle and even timid in conversation, he took a pleasure in asking questions, either to draw out others, or to add their reflections to his own vast knowledge. When he spoke, it was always in a tone of doubt, and his first words usually were, "I do not know." He respected the opinions of others, and was very far from laying down his own as a rule. Yet it was not easy to make him change them. Sometimes he even defended them with a degree of heat which continued to increase till he was sensible of some alteration in himself; he then immediately resumed his usual tranquillity.

Among the master-pieces which the world owes to his genius, his *Mécanique* is the most remarkable and the most important. His *Fonctions Analytiques* hold only the second place, notwithstanding the capability of the principal idea, and the beauty of the developments. A notation less commodious, and calculations more embarrassing, though more luminous, will prevent mathematicians from employing, except in difficult and doubtful cases, his symbols and names. It is sufficient that he has proved the legitimacy of the more expeditious processes of the differential and integral calculus, and he has himself followed the ordinary notation in the second edition of his *Mécanique*. This great work is entirely founded on the calculus of variations, of which he was the inventor. The whole flows from a single formula, and from a principle known before his time; but the utility of it was far from being suspected. This sublime composition includes all his preceding labours which could be connected with it. It is distinguished likewise by the philosophical spirit which reigns from one end of it to the other. The geometrical law of the celestial motions are deduced from

simple mechanical and analytical considerations. From those problems, which serve to analyse the true system of the world, the author passes to questions more difficult and complicated, which show the extent of his resources. We see there his new theory of the variations of arbitrary constant quantities in the motion of the planets, which so much distinguished the Memoirs of the Institute, where it proved that the author, at the age of 75, had not sunk from the rank which he had filled during so long a period in the opinion of all mathematicians.

Finally, it is remarked, that Lagrange was successively the founder of the Academy of Turin, director during 20 years of the Berlin Academy, foreign associate of the Academy of Sciences of Paris, member of the Imperial Institute, and of the Board of Longitude; and he was besides, senator and count of the empire, grand officer of the Legion of Honour, and Grand Cross of the Imperial Order of Re-Unions.

Abridged from Delambre's *Eloge of Lagrange*.

LAKE, a collection of water, inclosed in the cavity of some inland place, of a considerable extent and depth; as the lake of Geneva, &c.

LALANDE (JOSEPH JEROME LE FRANCAIS DE), an eminent professor of astronomy in the college of France, was born at Bourg, in the department of l'Aix, July 11, 1732, and he died at Paris, April 4, 1807, in the 75th year of his age. He was intended for the bar, and went to Paris for the study of Jurisprudence, when the view of the observatory inspired him with notions which deranged his former plan, and became the ruling passion of his life. He was kindly received by the celebrated astronomer le Monnier, by whose lessons he made such a rapid advance, that at the age of 19 he was nominated commissioner from the Academy of Sciences, to go to Berlin, to determine the parallax of the moon, while M. Lacaille was to perform the same operation at the Cape of Good-Hope. Soon after his return, he was appointed a member of the Academy of Sciences; from which time, every volume of their Memoirs contained some of his compositions, which were not limited to astronomical observations. He published the French edition of Halley's Tables, and the history of the comet of 1759, besides furnishing Clairaut with many calculations for the theory of the same. Being charged in 1760 with the compilation of the *Connaissance des Temps*, he quite changed the form of the work, giving it that which it bears at present; of which collection, he edited the 32 volumes from 1775 to 1807.

In 1764 appeared the first edition of his great work, the *Traité Astronomique*, a classical work, which he has since perfected, in 4 vols 4to. He composed all the astronomical articles for the *Yverdon Encyclopedia*, and new cast the whole for the *Encyclopédie Methodique*.

To his written instructions he joined, during 46 years, oral lessons. In 1761 he succeeded Delille in the astronomical chair at the college of France. In the midst of his labours, he drew up his *Voyage d'Italie*, his *Traité des Canaux*, and his *Bibliographie Astronomique*, a vast catalogue of all the works which have appeared on this science. In 1802, M. Lalande published the latter part of the new edition of Montucla's *History of Mathematics*, in 4 vols 4to; most of the last two volumes being prepared from Montucla's papers, with the assistance of Laplace, Lacroix, and other mathematicians.

In the year 1793, he published *Abrége de Navigation*, containing many valuable rules and tables. The Connois-

sance des Temps, from the year 7 to 12, or 1799 to 1804, contains his new catalogue of more than 12,000 stars. A few years before his death, viz., in 1802, he published a small collection for the pocket, of Tables of Logarithms, Sines, and Tangents, on the plan of Lacaille, but much inferior. And during the latter years of his life, he published annually a concise history of astronomy for the current year, which exhibited a summary of the most remarkable facts, discoveries, and inventions connected with the subject.

Lalande was certainly an excellent astronomer, and an active promoter of that science; but he had very little taste, and a very confined knowledge of mathematics in general. He considered himself, however, as the father of the mathematical sciences generally, and at his death, he founded the prize of a medal, which the Institute annually awards to the author of the best astronomical memoir, or the maker of the most curious observations. To the extraordinary ardour and activity of his character, he united a love for truth that approached the borders of fanaticism. To him every degree of concealment appeared unworthy of an honest man; and he therefore, without any reserve, uttered whatever might be his sentiments on all occasions. The high consideration which he obtained, would probably, with prudence and circumspection, have secured him an enviable respect to the end of his days; but the habit of speaking his mind, which he did not refrain from in the most stormy times, and on topics when he might, and indeed ought to have been silent, together with his bluntness in sometimes opposing the established systems of others, animated against him a crowd of detractors and enemies. His long and durable services in matters of science, were thus in a measure forgotten or neglected, in the contemplation of his dangerous speculations, and of the imprudent zeal with which he promulgated his opinions.

By his will, M. Lalande ordered his body to be dissected, and the skeleton to be placed in the Museum of Natural History. His relations however, regardless of the injunction, caused the body to be interred a few days after his death; on which occasion, the funeral was attended by the members of the National Institute.

LAMBERT (JOHN HENRY), an eminent mathematician, was a native of Mulhausen, in Alsace, where he was born, April 28, 1728. His education was rather confined, but he gave early indications of genius. At a very early period, he invented an arithmetical machine, a mercurial pendulum that vibrated for 27 minutes, arithmetical scales, and a machine for drawing in perspective. From 1748 to 1756, he was employed as tutor to the grandsons of M. le comte de Salis, at Coire. In 1757, the tutor and his pupils had passed the year in Holland, and he there published his treatise on the passage of Light. They afterwards travelled to Paris, where he was introduced to D'Alembert. In 1759, he published his *Perspective* at Zurich. From 1753 to 1760, he had several pieces published in the *Acta Helvetica*. In 1759, his *Photometry* was printed at Augsburg. In 1760, he collected the different pieces, still in a fugitive state, of his *Novum Organum*; but which was not published till 1764. In 1761, his treatise on the Properties of the Orbita of Comets was printed at Augsburg. He was admitted a pensioner of the Berlin Academy in 1765; from which time, to his death, in 1777, he furnished many memoirs for the several volumes of that academy.—The scientific knowledge of this gentleman

was very considerable; and he had great independence of mind, with a very warm and vivid imagination.

LAMMAS-DAY, the 1st of August; so called, according to some, because lambs then grow out of season, as being too large. Others derive it from a Saxon word, signifying loaf-mass, because on that day our forefathers made an offering of bread prepared with new wheat. It is celebrated by the Romish church in memory of St. Peter's imprisonment.

LAMPÆDIAS, a kind of bearded comet, resembling a burning lamp, being of several shapes; for sometimes its flame or blaze runs tapering upwards like a sword, and sometimes it is double or treble pointed.

LANDEN (John), an eminent mathematician, was born at Peakirk, near Peterborough in Northamptonshire, in January 1719. He became very early a proficient in the mathematics, for we find him a very respectable contributor to the Ladies' Diary in 1744; and he was soon among the foremost of those who then contributed to the support of that small but valuable publication, in which almost every English mathematician, who has arrived at any degree of eminence for the best part of that century, has contended for fame at one time or other of his life. Mr. Landen continued his contributions to it at times, under various signatures, till within a few years of his death.

It has been frequently observed, that the histories of literary men consist chiefly of the history of their writings; and the observation was never more fully verified, than in the present article concerning Mr. Landen.

In the 48th volume of the Philosophical Transactions, for the year 1754, Mr. Landen gave An investigation of some theorems which suggest several very remarkable properties of the Circle, and are at the same time of considerable use in resolving fractions, the denominators of which are certain multinomials, into more simple ones, and by that means facilitate the computation of fluents.

In the year 1755, he published a volume of about 160 pages, entitled Mathematical Lucubrations. The title to this publication was made choice of, as a means of informing the world, that the study of the mathematics was at that time rather the pursuit of his leisure hours, than his principal employment: and indeed it continued to be so, during the greatest part of his life; for about the year 1762 he was appointed agent to Earl Fitzwilliam, an employment which he resigned only two years before his death. These lucubrations contain a variety of tracts relative to the rectification of curve lines, the summation of series, the finding of fluents, and many other points in the higher parts of the mathematics.

About the latter end of the year 1757, or the beginning of 1758, he published proposals for printing by subscription The Residual Analysis, a new branch of the algebraic art: and in 1758 he published a small tract, entitled A Discourse on the Residual Analysis; in which he resolved a variety of problems, to which the method of fluxions had usually been applied, by a mode of reasoning entirely new: he also compared these solutions with others derived from the fluxionary method; and showed that the solutions by his new method were commonly more natural and elegant than the fluxionary ones.

In the 51st volume of the Philosophical Transactions, for the year 1760, he gave a new method of computing the sums of a great number of infinite series.

In 1764, he published the first book of The Residual Analysis. In this treatise, besides explaining the prin-

ciples which his new analysis was founded on, he applied it, in a variety of problems, to drawing tangents, and finding the properties of curve lines; to describing their involutes and evolutes, finding the radius of curvature, their greatest and least ordinates, and points of contrary flexure; to the determination of their cusps, and the drawing of asymptotes: and he proposed, in second book, to extend the application of this new analysis to a great variety of mechanical and physical subjects. The papers which were to have formed this book lay long by him; but he never found leisure to put them in order for the press.

In the year 1766, Mr. Landen was elected a Fellow of the Royal Society. And in the 58th volume of the Philosophical Transactions, for the year 1768, he gave a specimen of a new method of comparing curvilinear areas; by means of which many areas are compared, that did not appear to be comparable by any other method: a circumstance of no small importance in that part of natural philosophy which relates to the doctrine of motion.

In the 60th volume of the same work, for the year 1770, he gave some new theorems for computing the whole areas of curve lines, where the ordinates are expressed by fractions of a certain form, in more concise and elegant manner than had been done by Cotes, De Moivre, and others who had considered the subject before him.

In the 61st volume, for 1771, he has investigated several new and useful theorems for computing certain fluents, which are assignable by arcs of the conic sections; a subject which had been considered before, both by MacLaurin and Dalembert; but some of the theorems that were given by these celebrated mathematicians, being in part expressed by the difference between an hyperbolic arc and its tangent, and that difference being not directly attainable when the arc and its tangent both become infinite, as they will do when the whole fluent is wanted, though such fluent be finite; these theorems therefore fail in such cases, and the computation becomes impracticable without further help. This defect Mr. Landen removed, by assigning the limit of the difference between the hyperbolic arc and its tangent, while the point of contact is supposed to be removed to an infinite distance from the vertex of the curve. And he concludes the paper by stating a curious and remarkable property relating to pendulous bodies, which is deducible from those theorems. In the same year he published Animadversions on Dr. Stewart's Computation of the Sun's Distance from the Earth.

In the 65th volume of the Philosophical Transactions, for 1775, he gave the investigation of a general theorem, which he had promised in 1771, for finding the length of any curve of a conic hyperbola by means of two elliptic arcs; and he observes, that by the theorems there investigated, both the elastic curve and the curve of equable recess from a given point, may be constructed in those cases where Maclaurin's elegant method fails.

In the 67th volume, for 1777, he gave a new theory of the motion of bodies revolving about an axis in free space, when that motion is disturbed by some extraneous force, either percussive or accelerative. At this time he did not know that the subject had been treated by any person before him, and he considered only the motion of a sphere, spheroid, and cylinder. After the publication of this paper however he was informed, that the doctrine of rotatory motion had been considered by Dalembert; and on procuring that author's Opuscules Mathématiques, he there learned that Dalembert was not the only one who

had considered the matter before him; for Dalembert there speaks of a mathematician, though he does not mention his name, who, after reading what had been written on the subject, doubted whether there could be any solid whatever, besides the sphere, in which any line, passing through the centre of gravity, will be a permanent axis of rotation. In consequence of this, Mr. Landen took up the subject again; and though he did not then give a solution to the general problem, viz., "to determine the motions of a body of any form whatever, revolving without restraint about any axis passing through its centre of gravity," he fully removed every doubt of the kind which had been started by the person alluded to by Dalembert, and pointed out several bodies which, under certain dimensions, have that remarkable property. This paper is given, among many others equally curious, in a volume of Memoirs, which he published in the year 1780. That volume is also enriched with a very extensive appendix, containing theorems for the calculation of fluents; which are more complete and extensive than those that are found in any author before him.

In 1781, 1782, and 1783, he published three small tracts on the summation of converging series; in which he explained and showed the extent of some theorems which had been given for that purpose by De Moivre, Stirling, and his old friend Thomas Simpson, in answer to some things which he thought had been written injurious to the fame of those excellent mathematicians. It was the opinion of some, that Mr. Landen did not show less mathematical skill in explaining and illustrating these theorems, than he has done in his writings on original subjects; and that the authors of them were as little aware of the extent of their own theorems, as the rest of the world were, before Mr. Landen's ingenuity made it obvious to all.

About the beginning of the year 1782, Mr. Landen had made such improvements in his theory of rotatory motion, as enabled him, he thought, to give a solution of the general problem mentioned above; but finding the result of it to differ very materially from the result of the solution which had been given of it by Dalembert, and not being able to see clearly where that gentleman in his opinion had erred, he did not venture to make his own solution public. In the course of that year, however, having procured the Memoirs of the Berlin Academy for 1757, which contain M. Euler's solution of the problem, he found 'that this gentleman's solution gave the same result as had been deduced by Dalembert; but the perspicuity of Euler's manner of writing enabled him to discover where he had differed from his own, which the obscurity of the other did not do. The agreement, however, of two writers of such established reputation as Euler and Dalembert made him long dubious of the truth of his own solution, and induced him to revise the process again and again with the utmost circumspection; and being every time more convinced that his own solution was right, and theirs wrong, he at length gave it to the public, in the 75th volume of the Philosophical Transactions, for 1785.

The extreme difficulty of the subject, joined to the concise manner in which Mr. Landen had been obliged to give his solution, to confine it within proper limits for the Transactions, rendered it too difficult, or at least too laborious a task for most mathematicians to read it; and this circumstance, joined to the established reputation of Euler and Dalembert, induced many to think that their

solution was right, and Mr. Landen's wrong; and there did not want attempts to prove it; particularly a long and ingenious paper by the learned Mr. Wildbore, a gentleman of very distinguished talents and experience in such calculations: this paper is given in the 80th volume of the Philosophical Transactions, for the year 1790, in which he agrees with the solutions of Euler and Dalembert, and against that of Mr. Landen. This determined the latter to revise and extend his solution, and give it at greater length, to render it more generally understood. About this time also he met by chance with the late Frisi's Cosmographiae Physicæ et Mathematicæ; in the second part of which there is a solution of this problem, agreeing in the result with those of Euler and Dalembert. Here Mr. Landen learned that Euler had revised the solution which he had given formerly in the Berlin Memoirs, and given it another form, and at greater length, in a volume published at Rostoch and Gryphiswald in 1765, entitled, *Theoria Motus Corporum Solidorum seu Rigidorum*. Having therefore procured this book, Mr. Landen found the same principles employed in it, and of course the same conclusion resulting from them, as in M. Euler's former solution of the problem. But notwithstanding that there were thus a coincidence of at least four most respectable mathematicians against him, Mr. Landen was still persuaded of the truth of his own solution, and prepared to defend it. And as he was convinced of the necessity of explaining his ideas on the subject more fully, so he now found it necessary to lose no time in setting about it. He had for several years been severely afflicted with the stone in the bladder, and towards the latter part of his life to such a degree as to be confined to his bed for more than a month at a time: yet even this dreadful disorder did not extinguish his ardour for mathematical studies; for the second volume of his Memoirs, lately published, was written and revised during the intervals of his disorder. This volume, besides a solution of the general problem concerning rotatory motion, contains the resolution of the problem relating to the motion of a top; with an investigation of the motion of the equinoxes, in which Mr. Landen has first of any one pointed out the cause of Sir Isaac Newton's mistake in his solution of this celebrated problem; and some other papers of considerable importance. He just lived to see this work finished, and received a copy of it the day before his death, which happened on the 15th of January 1790, at Milton, near Peterborough, in the 71st year of his age.

LANTERN (MAGIC). See MAGIC LANTERN.

LARBOARD, the left-hand side of a ship, when a person stands with his face towards the head.

LARMIER, in Architecture, a flat square member of the cornice below the cimasmus, and jets out farthest; being so called from its use, which is to disperse the water, and cause it to fall at a distance from the wall, drop by drop, or, as it were, by tears; *larme* in French signifying a tear.

LATENT Heat, is that which is insensible, inactive, dormant, &c.

LATERAL EQUATION, in Algebra, is the same with simple equation. It has but one root, and may be constructed by right lines only.

LATITUDE, in Geography, or Navigation, the distance of a place from the equator; or an arch of the meridian, intercepted between its zenith and the equator. Hence the latitude is either north or south, according as the place is

on the north or south side of the equator: thus London is said to be in $51^{\circ} 31'$ of north latitude. Circles parallel to the equator are called *parallels of latitude*, because they show the latitudes of places by their intersections with the meridian. The latitude of a place is equal to the elevation of the pole above the horizon of the place: and hence these two terms are used indifferently for each other. This will be evident from the figure, where the circle ZHQ is the meridian, z the zenith of the place, HO the horizon, EQ the equator, and P the pole, then is ZE the latitude, and PO the elevation of the pole above the horizon. And because $PE = zO$, being each a quadrantial arc, if the common part PZ be taken from both, there will remain the latitude $ZE = PO$ the elevation of the pole.—Hence we have a method of measuring the circumference of the earth, or of determining the quantity of a degree on its surface; for by measuring directly northward or southward, till the pole be one degree higher or lower, we have the number of miles in a degree of a great circle on the surface of the earth; and consequently multiplying that by 360, will give the number of miles round the whole circumference of the earth. The knowledge of the latitude of the place, is of the utmost consequence, in geography, navigation, and astronomy; it may be proper therefore to lay down some of the best modes of determining it, both by sea and land.

1st. One method is, to find the height of the pole, to which the latitude is equal, by means of the pole star, or any other circumpolar star, thus: Either draw a true meridian line, or find the times when the star is on the meridian, both above and below the pole; then at these times, with a quadrant, or other fit instrument, take the altitudes of the star; or take the same when the star comes upon your meridian line; which will be the greatest and least altitude of the star: then shall half the sum of the two be the elevation of the pole, or the latitude sought.—For, if abc be the path of the star about the pole P , z the zenith, and HO the horizon: then is ao the altitude of the star upon the meridian when above the pole, and co the same when below the pole; hence, because $ar = cr$, therefore $ao + co = 2or$, hence the height of the pole OP , or latitude of z , is equal to half the sum of ao and co .

2d. A second method is by means of the declination of the sun, or a star, and one meridian altitude of the same, thus: Having with a quadrant, or other instrument, observed the zenith distance zd of the luminary; or else its altitude nd , and taken its complement zd ; then to this zenith distance, add the declination de when the luminary and place are on the same side of the equator, or subtract it when on different sides, and the sum or difference will be the latitude ez sought. But note, that all altitudes observed, must be corrected for refraction and the dip of the horizon, and for the semidiameter of the sun, when that is the luminary observed.

Many other methods of observing and computing the latitude may be seen in Robertson's Navigation; see book 5 and book 9. See also the Nautical Almanac for 1771; and Mr. Brinkley's tables and rules for the same purpose, in the Nautical Almanac for the year 1797. Mr. Richard Graham contrived an ingenious instrument for taking the latitude of a place at any time of the day. See Philos. Trans. No. 435, or my Abr. vol. 7. pa. 673.

VOL. I.

LATITUDE, in Astronomy, as of a star or planet, is its distance from the ecliptic, being an arch of a circle of latitude, reckoned from the ecliptic towards its poles, either north or south. Hence, the astronomical latitude is quite different from the geographical, the former measuring from the ecliptic, and the latter from the equator, so that this latter answers to the declination in astronomy, which measures from the equinoctial. The sun has no latitude, being always in the ecliptic; but all the stars have their several latitudes, and the planets are continually changing their latitudes, sometimes north and sometimes south, crossing the ecliptic from the one side to the other; the points in which they cross the ecliptic being called the nodes of the planet, and in these points it is that they may appear to pass over the face of the sun, or behind his body, viz. when they come both to this point of the ecliptic at the same time.

Circle of Latitude, is a great circle passing through the poles of the ecliptic, and consequently perpendicular to it, as the meridians are perpendicular to the equator, and pass through its poles.

Latitude, of the Moon, North ascending, is when she proceeds from the ascending node towards her northern limit, or greatest elongation.

Latitude, North descending, is when the moon returns from her northern limit towards the descending node.

Latitude, South descending, is when she proceeds from the descending node towards her southern limit.

Latitude, South ascending, is when she returns from her southern limit towards her ascending node. And the same is to be understood of the planets.

Heliocentric Latitude of a planet, is its latitude, or distance from the ecliptic, such as it would appear from the sun.—This, when the planet comes to the same point of its orbit, is always the same, or unchangeable.

Geocentric Latitude of a planet, is its latitude as seen from the earth.—This, though the planet be in the same point of its orbit, is not always the same, but alters according to the position of the earth, in respect to the planet. The latitude of a star is altered only by the aberration of light, and the secular variation of latitude.

Difference of Latitude, is an arc of the meridian, or the nearest distance between the parallels of latitude of two places. When the two latitudes are of the same name, either both north or both south, subtract the less latitude from the greater, to give the difference of latitude; but when they are of different names, add them together for the difference of latitude.

Middle Latitude, is the middle point between two latitudes or places; and is found by taking half the sum of the two.

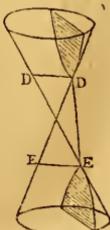

Parallax of Latitude. See PARALLAX.

Refraction of Latitude. See REFRACTION.

Latus Rectum, in Conic Sections, the same with parameter; which sec.

Latus Transversum, of the hyperbola, is the right line between the vertices of the two opposite sections; or that part of their common axis lying between the two opposite cones; as the line DE . It is the same as the transverse axis of the hyperbola, or opposite hyperbolae.

Latus Primarium, a right line, DD , or EE , drawn through the vertex of the section of a cone, within the same, and parallel to the base.

LEAGUE, an extent of three miles in length. A nautical league, or three nautical miles, is the 20th part of a degree of a great circle.

LEAP-YEAR, the same as BISSEXTILE; which see. It is so called from its leaping a day more than year than in a common year; consisting of 366 days, and a common year only of 365. This happens every 4th year, except only such complete centuries as are not exactly divisible by 4; such as the 17th, 18th, 19th, 21st &c, centuries, because 17, 18, 19, 21, &c, cannot be divided by 4 without a remainder.

To find Leap-Year, &c. Divide the number of the year by 4; then if 0 remain, it is leap-year; but if 1, 2, or 3 remain, it is so many after leap-year. Or the rule is sometimes thus expressed, in these two memorial verses:

Divide by 4; what's left shall be,

For leap-year 0; for past 1, 2, or 3.

Thus if it be required to know what year 1814 is:

then 4) 1814 (453

2 remains;

so that 2 remaining, shows that 1814 is the 2d year after leap-year. And to find what year 1816 is:

then 4) 1816 (454

here 0 remaining, shows that 1816 is a leap-year.

LEE, a term in Navigation, signifying that side, or quarter, which is from the wind.

LEE-WAY, of a ship, is the angle made by the point of the compass steered on, and the real line of the ship's way, occasioned by contrary winds and a rough sea. All ships are apt to make some lee-way; so that something must be allowed for it, in casting up the log-board. But the lee-way made by different ships, under similar circumstances of wind and sails, is different; and even the same ship, with different lading, and having more or less sail set, will have more or less lee-way. The usual allowances for it are these, as they were given by Mr. John Buckler, to the late ingenious Mr. William Jones, who first published them in 1702 in his Compendium of Practical Navigation. 1st, When a ship is close-hauled, has all her sails set, the sea smooth, and a moderate gale of wind, it is then supposed she makes little or no lee-way. 2d, Allow 1 point, when it blows so fresh that the small sails are taken in. 3d, Allow 2 points, when the top-sail must be close reefed. 4th, Allow $2\frac{1}{2}$ points, when one topsail must be handed. 5th, Allow $3\frac{1}{2}$ points, when both topsails must be taken in. 6th, Allow 4 points, when the fore-course is handed. 7th, Allow 5 points, when trying under the mainsail only. 8th, Allow 6 points, when both main and fore-courses are taken in. 9th, Allow 7 points, when the ship tries a hull, or with all sails handed.

When the wind has blown hard in either quarter, and shifts across the meridian into the next quarter, the lee-way will be lessened. But in all these cases, respect must be had to the roughness of the sea, and the trim of the ship. And hence the mariner will be able to correct his course.

LEGS, of a Triangle. When one side of a triangle is taken as the base, the other two are sometimes called the legs. The term is more frequently used for the base and perpendicular of a right-angled triangle, or the two sides about the right angle.

Hyperbolic LEGS, are the parts of a curve line that partake of the nature of the hyperbola, or having asymptotes.

LEIBNITZ (GODFREY-WILLIAM), an eminent mathematician and philosopher, was born at Leipsic in Saxony

in 1646. At the age of 15, he applied himself to the study of the mathematics at Leipzig and Jena; and in 1663, maintained a thesis De Principiis Individuationis. The year following he was admitted master of arts. He read with great attention the Greek philosophers; and endeavoured to reconcile Plato with Aristotle, as he afterwards did Aristotle with Descartes. But the study of the law was his principal view; in which faculty he was admitted bachelor in 1665. The year following he would have taken the degree of doctor; but was refused it on pretence that he was too young, though in reality because he had raised himself several enemies by rejecting the principles of Aristotle and the schoolmen. On this he repaired to Altorf, where he maintained a thesis De Casibus Perplexis, with such applause, that he had the degree of doctor conferred on him.

In 1672 he went to Paris, to manage some affairs at the French court for the baron Boinebourg. Here he became acquainted with all the literati, and made farther and considerable progress in the study of mathematics and philosophy, chiefly, as he says, by the works of Pascal, Gregory St. Vincent, and Huygens. In this course, having observed the imperfection of Pascal's arithmetical machine, he invented a new one, as he called it, which was approved of by the minister Colbert, and the Academy of Sciences, in which he was offered a seat as a member, but refused the offers made to him, as it would have been necessary to embrace the Catholic religion.

In 1673 he came over to England; where he became acquainted with Mr. Oldenburg, secretary of the Royal Society, and Mr. John Collins, a distinguished member of the Society; from whom it seems he received some hints of the method of fluxions, which had been invented, in 1664 or 1665, by the then Mr. Isaac Newton, which probably laid the foundation of his Differential Calculus. The same year he returned to France, where he resided till 1676, when he again passed through England and Holland, in his journey to Hanover, where he proposed to settle.

In 1700 he was admitted a member of the Royal Academy of Sciences at Paris: and in the same year the elector of Brandenburg, afterwards king of Prussia, founded an academy at Berlin by his advice; of which he was appointed perpetual president, though his affairs would not permit him to reside constantly at that place. Besides the office of privy counsellor of justice, which the elector of Hanover had given him, the emperor appointed him, in 1711, aulic counsellor; and the czar made him privy counsellor of justice, with a pension of 1000 ducats. Leibnitz undertook at the same time to establish an academy of sciences at Vienna; but the plague prevented the execution of it. However, the emperor, as a mark of his favour, settled a pension on him of 2000 florins, and promised him one of 4000 if he would come and reside at Vienna; an offer he was inclined to comply with, but was prevented by his death.

The elector of Hanover being raised to the throne of Great Britain, Leibnitz visited that place the latter end of 1714, when he received particular marks of friendship from the king, and was frequently at court. He now was engaged in a dispute with Dr. Samuel Clarke, on the subjects of free will, the reality of space, and other philosophical subjects; which was conducted with great candour and learning; and the papers that were published by Clarke, will ever be esteemed by men of genius and learn-

ing. The controversy ended only with the death of Leibnitz, Nov. 14, 1716, which was occasioned by the gout and stone, in the 70th year of his age.

In person he was of a middle stature, and a thin habit of body. He had a studious air, and a sweet aspect, though near-sighted. He was indefatigably industrious to the end of his life: he ate and drank little: hunger alone marked the time of his meals, and his diet was plain and strong. He had a very good memory, and it was said could repeat the *Aeneid* from beginning to end. What he wanted to remember, he wrote down, and never read it afterwards. He was never married, nor ever seems to have entertained the idea but once, when he was about 50 years old; and the lady desiring time to consider of it, gave him an opportunity of doing the same: he used to say, "that marriage was a good thing, but a wise man ought to consider of it all his life."

Leibnitz was author of a great multitude of writings; several of which were published separately, and many others in the memoirs of different academies. He invented a binary arithmetic, and many other ingenious matters. His claim to the invention of fluxions, has been spoken of under that article. Hanschius collected, with great care, every thing that Leibnitz had said, in different passages of his works, on the principles of philosophy; and formed of them a complete system, under the title of G. G. Leibnitii Principia Philosophiae more geometrico demonstrata &c, 1728, in 4to. A collection of our author's letters appeared in 1734 and 1735, entitled, *Epistolæ ad diversos theologici, iuridici, medici, philosophicæ mathematici, historici, et philologicæ argumenti e mss. auctoris: cùm annotationibus suis primum divulgavit Christianus Cortholus.* But all his works were collected, distributed into classes by M. Dutens, and published at Geneva in 6 large volumes 4to, in 1768, entitled, *Gothofredi Guillelmi Leibnitii Opera Omnia &c.*

LEIBNITZIAN PHILOSOPHY, or the philosophy of Leibnitz, is a system formed and published by its author in the last century, partly in emendation of the Cartesian, and partly in opposition to the Newtonian doctrine. In this philosophy, the author retained the Cartesian subtle matter, with the vortices and universal plenum; and he represented the universe as a machine that should proceed for ever, by the laws of mechanism, in the most perfect state, by an absolute inviolable necessity. After Newton's philosophy was published, in 1687, Leibnitz printed an essay on the celestial motions in the *Act. Erud.* 1689, where he admits the circulation of the ether with Descartes, and of gravity with Newton; though he has not reconciled these principles, nor shown how gravity arose from the impulse of this ether, nor how to account for the planetary revolutions in their respective orbits. His system is also defective, as it does not reconcile the circulation of the ether with the free motions of the comets in all directions, or with the obliquity of the planes of the planetary orbits; nor resolve other objections to which the hypothesis of the vortices and a plenum is liable.

Soon after the period just mentioned, the dispute commenced concerning the invention of the method of fluxions, which led M. Leibnitz to take a very decided part in opposition to the philosophy of Newton. From the goodness and wisdom of the Deity, and his principle of a sufficient reason, he concluded, that the universe was a perfect work, or the best that could possibly have been

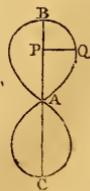

made; and that other things, which are evil or incommodeous, were permitted as necessary consequences of what was best: that the material system, considered as a perfect machine, can never fall into disorder, or require to be set right; and to suppose that God interposes in it, is to lessen the skill of the author, and the perfection of his work. He expressly charges an impious tendency on the philosophy of Newton, because he asserts, that the fabric of the universe and course of nature could not continue for ever in its present state, but in process of time would require to be re-established or renewed by the hand of its first framer. The perfection of the universe, in consequence of which it is capable of continuing for ever by mechanical laws in its present state, led M. Leibnitz to distinguish between the quantity of motion and the force of bodies; and, while he owns, in opposition to Descartes, that the former varies, to maintain that the quantity of force is for ever the same in the universe; and to measure the forces of bodies by the squares of their velocities.

M. Leibnitz proposes two principles as the foundation of all our knowledge; the first, that it is impossible for a thing to be, and not to be at the same time, which he says is the foundation of speculative truth; and secondly, that nothing is without a sufficient reason why it should be so, rather than otherwise; and by this principle he says we make a transition from abstracted truths to natural philosophy. Hence he concludes that the mind is naturally determined, in its volitions and elections, by the greatest apparent good, and that it is impossible to make a choice between things perfectly like, which he calls Indiscernibles; whence he infers, that two things perfectly like could not have been produced even by the Deity himself: and one reason why he rejects a vacuum, is because the parts of it must be supposed perfectly like to each other. For the same reason too, he rejects atoms, and all similar parts of matter, to each of which, though divisible ad infinitum, he ascribes a Monad (*Act. Lipsie 1698, pa. 435*) or active kind of principle, endowed with perception and appetite. The essence of substance he places in action or activity, or, as he expresses it, in something that is between acting and the faculty of acting. He affirms that absolute rest is impossible, and holds that motion, or a sort of nisus, is essential to all material substances. Each monad he describes as representative of the whole universe from its point of sight; and yet he tells us, in one of his letters, that matter is not a substance, but a substantiatum, or phénoméné bien fondé. See also Maclaurin's View of Newton's Philosophical Discoveries, book 1, chap. 4.

LEMMA, is a term chiefly used by mathematicians, and signifies a proposition, previously laid down to prepare the way for the more easy apprehension of the demonstration of some theorem, or the construction of some problem.

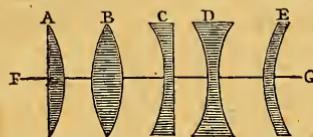

LEMNISCATE, the name of a curve in the form of the figure of 8. If we call AP, x ; PQ, y , and the constant line AB or AC, a ; the equation $ay = x\sqrt{(a^2 - x^2)}$, or $a^2y^4 = a^2x^2 - x^4$, expressing a line of the 4th degree, will denote a lemniscate, having a double point in the point A . There may be other lemniscates, as the ellipse of Cassini, &c; but that above defined is the simplest of them.

It easily appears that this curve is quadrable. For
4 Y 2

since $ay = x\sqrt{(a^2 - x^2)}$, therefore the fluxion of the curve or $y\dot{x}$ is $= \frac{x}{a}\sqrt{(a^2 - x^2)} \frac{d}{dx}$; the fluent of which is $\frac{1}{3}a^2 - \frac{1}{3a} \cdot (a^2 - x^2)^{\frac{3}{2}}$ for the general area of the curve; which, when x is $= a$, becomes barely $\frac{1}{3}a^2 = AQB$.

LENS. a piece of glass or other transparent substance, having its two surfaces so formed that the rays of light, in passing through it, have their direction changed, and made to converge and tend to a point beyond the lens, or to become parallel after converging or diverging, or lastly to diverge as if they had proceeded from a point before the lens. Some lenses are convex, or thicker in the middle; others concave, or thinner in the middle; while others are plano-convex, or plano-concave; and some again are convex on one side and concave on the other, which are called meniscuses, the properties of which see under that word. When the particular figure is not considered, a lens that is thickest in the middle is called a convex lens; and that which is thinnest in the middle is called a concave lens, without further distinction. These several forms of lenses are represented in the annexed figure:

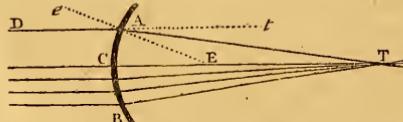

where **A**, **B** are convex lenses, and **C**, **D**, **E** are concave ones; also **A** is a plano-convex, **B** is convexo-concave, **C** is plano-concave, **D** is concavo-concave, and **E** is a meniscus.

In every lens, the right line perpendicular to the two surfaces, is called the Axis of the lens, as **F G**; the points where the axis cuts the surface, are called the Vertices of the lens; also the middle point between them is called the Centre; and the distance between them, is the Diameter. Some confine lenses within the diameter of half an inch; and such as exceed that thickness, they call Lenticular Glasses.—Lenses are either blown or ground.

Blown LENSES, are small globules of glass, melted in the flame of a lamp or taper. See **MICROSCOPE**.

Ground LENSES, are such as are ground or rubbed into the desired shape, and then polished. For a method of grinding them, and description of a machine for that purpose, see *Philos. Trans. vol. xli. pa. 555*, or my *Abr. viii. 451*.

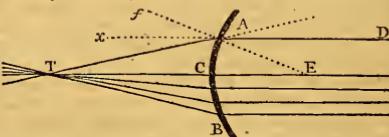

Maurolyc first delivered something relative to the nature of lenses; but we are chiefly indebted to Kepler for explaining the doctrine of refraction through mediums of different forms, the chief substance of which may be comprehended in the cases following:

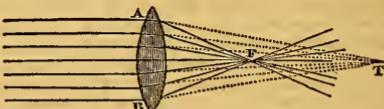

Let **DA** be a ray of light falling on a convex dense medium, having its centre at **E**. When the ray arrives at **A**, it will not proceed in the same direction **AT**; but it will be there bent, and thrown into a direction **AT**, nearer the

perpendicular **AE**. In the same manner, another ray falling on **B**, at an equal distance on the other side of the vertex **c**, and parallel to the former ray **DA**, will be refracted into the same point **T**. And it will also be found, that all the intermediate parallel rays will converge to the same point, very nearly.

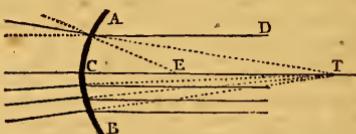

On the other hand, if the rays fall parallel on the inside of this denser medium, as in the figure below, they will tend from the perpendicular **EAf**; and converge to a point **T** in the air, or any rarer medium. Also the ray incident on **B**, at the same distance from the vertex **c**, will converge to the same place **T**, together with all the intermediate parallel rays.

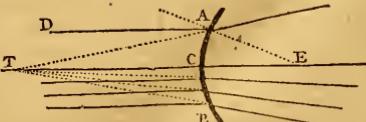

Since therefore rays are made to converge when they pass either from a rarer or a denser medium terminated by a convex surface, and converge again when they pass from the same medium convex towards the rarer, a lens which is convex on both sides must, on both accounts, make parallel rays converge to a point beyond it. Thus, the parallel rays between **A** and **B**, falling on

the convex surface of the glass **AB**, would in that dense medium have converged to **T**; but that medium being terminated by another convex surface, they will be made more converging, and be collected at some place **r**, nearer to the lens.

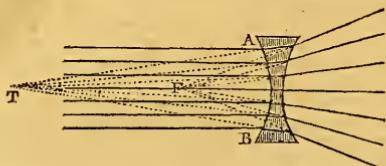

Again, to explain the effects of a concave glass, let **AB** be the concave side of a dense medium, the centre of concavity being at **E**. In this case, **DA** will be refracted towards the perpendicular **EA**; and so likewise will the ray incident at **B**; in consequence of which they will diverge from one another within the dense medium. The intermediate rays will also diverge more or less, as they recede from the axis **CE**; which, being in the perpendicular, will go straight on.

If the rays be parallel within the dense medium, they will diverge when they pass from thence into a rarer me-

dium, through a concave surface. For the ray DA will be refracted from the perpendicular AE , as will also the ray that is incident at B , together with all the intermediate rays, in proportion to their distance from the axis or central ray TC .

Therefore, if a dense medium, as the glass AB , be terminated by two concave surfaces, parallel rays passing through it will be made to diverge by both the sides of it. Thus the first surface AB will make them diverge as if they had come from the point T ; and with the effect of the second surface added to this, they will diverge as from a nearer point, r .

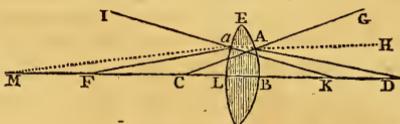

It was Kepler, who by these investigations first gave a clear explanation of the effects of lenses, in making the rays of a pencil of light converge or diverge. He showed that a plano-convex lens makes rays, that were parallel to its axis, meet at the distance of the diameter of the sphere of convexity; but that if both sides of the lens be equally convex, the rays will have their focus at the distance of the radius of the circle corresponding to that degree of convexity. But he did not investigate any rule for the foci of lenses unequally convex. He only says, in general, that they will fall somewhere in the medium, between the foci belonging to the two different degrees of convexity. It is to Cavalieri that we owe this investigation; who laid down this rule: As the sum of both the diameters is to one of them, so is the other to the distance of the focus. And it is to be noted that all these rules, concerning convex lenses, are applicable to those that are concave, with this difference, that the focus is on the contrary side of the glass. See Montucla, vol. 2, pa. 176; or Priestley's Hist. of Vision, pa. 63, 4to.

On this principle it was not difficult to find the foci of pencils of rays issuing from any point in the axis of the lens; since those that are parallel will meet in the focus; and if they issue from the focus, they will be parallel on the other side. If they issue from a point between the focus and the glass, they will continue to diverge after passing the lens, but less than before; while those that come from beyond the focus, will converge after passing the glass, and will meet in a place beyond the opposite focus. This philosopher particularly observed, that rays which issue from twice the distance of the focus, will meet at the same distance on the other side. The most important of these observations have been already illustrated by proper figures, and from them the rest may be easily conceived. Later optical writers have assigned the distances at which rays will meet, that issue from any other place in the axis of a lens; but Kepler was too much intent upon his astronomical and other pursuits, to pay much attention to geometry. Montucla gives the following rule concerning this subject: As the excess of the distance of the object from the glass, above the distance of the focus, is to the distance of the focus; so is this distance, to the place of convergency beyond the glass. And

the same rule will find the point of divergency, when the rays issue from any place between the lens and the focus; for then the excess of the distance of the object from the glass, above that of the focus, is negative, which is the same distance taken the contrary way. Montucla, vol. 2, pa. 177.

And from the principle above-mentioned, it will not be difficult to understand the application of lenses, in the rationale of telescopes and microscopes. And on these principles also is founded the structure of refracting burning glasses, by which the sun's light and heat are exceedingly augmented in the focus of the lens, whether convex or plano-convex; since the rays, falling parallel to the axis of the lens, are reduced into a much narrower compass; so that it is no wonder they burn some bodies, melt others, and produce other extraordinary phenomena.

In the Philos. Trans. vol. xvii. 960, or my Abr. iii. 593, Dr. Halley gives an ingenious investigation of the foci of rays refracted through any lenses, nearly as follows:

Let BEL , be a double convex lens, c the centre of the segment EB , and K the centre of the segment EL ; BL the thickness or diameter of the lens, and D a point in the axis; it is required to find the point r , or focus, where the rays proceeding from D shall be collected, after being refracted through the lens at A and a , points very near to the axis BL . Put the distance DA or $DB = d$, the radius CA or $CB = r$, and the radius KA or $KL = R$; also the thickness of the lens $BL = t$, and m to n the ratio of the sine of the angle of incidence DAG to the sine of the refracted angle HAG or CAM ; or m to n will be the ratio of those angles themselves nearly, since very small angles are to each other in the same ratio as their sines. Hence

$$\begin{aligned} m & \text{ is as the angle } DAG \text{ or } DAC, \\ n & \text{ is as the angle } HAG \text{ or } MAC, \end{aligned}$$

and because in this case the sides are as their opposite angles, therefore $DC : DA :: \angle DAC : \angle C$, or $d + r : d :: \frac{dm}{d+r}$ which is as the $\angle C$; from this take n or the $\angle MAC$,

and there remains $\frac{dm - dn - nr}{d+r}$ as the $\angle N$; hence again

$$\angle M : \angle C :: CA : MA \text{ or } MB, \text{ that is } \frac{dm - dn - nr}{d+r} : \frac{dm}{d+r} :: \frac{mnr}{(m-n) \cdot d - nr} = MA \text{ or } MB; \text{ which shows in what}$$

point the rays would be collected after one refraction, viz, when nr is less than $(m-n) \cdot d$. But when nr is $= (m-n) \cdot d$, the point would be at an infinite distance, or the rays will be parallel to the axis; and when nr is greater than $(m-n) \cdot d$, then MB is negative, or M falls on the other side of the lens beyond D , and the rays still continue to diverge after the first refraction.

The point M being now found, to or from which the rays proceed after the first refraction, and $BM - BL$ being thus given, which call D , by a process like the former it follows that FL , or the focal distance sought, is equal to

$$\frac{nDR}{(m-n) \cdot d + nr} = f. \text{ And here, instead of } D \text{ substituting }$$

$\frac{mR - LR}{(m-n) \cdot d - nr} = t$, and putting p for $\frac{n}{m-n}$, the same theorem will become

$$\frac{(mpdr - ndr + npr) \times R}{mdr + mnr - (m-n) \cdot dt + nrt} = f$$
, the focal distance sought, in its most general form, including the thickness of the lens; being the universal rule for the foci of double convex glasses exposed to diverging rays.

But if t the thickness of the lens be rejected, as not sensible, the rule will be much shorter, viz,

$$\frac{pdR}{dr + dr - pr} = f.$$

If therefore the lens consist of glass, whose refraction is as 3 to 2, it will be $\frac{2drR}{dr + dr - 2rR} = f$. And if it be of water, whose refraction is as 4 to 3, it will be $\frac{3drR}{dr + dr - 3rR} = f$. But, if the lens could be made of diamond, whose refraction is as 5 to 2, it would be $\frac{2drR}{3dr + 2dr - 2rR} = f$.

If the incident rays, instead of diverging, be converging, the distance dB or d will be negative, and then the theorem for a double convex glass lens will be $\frac{-2drR}{dr - dr - 2rR}$

or $\frac{2drR}{dr + dr + 2rR} = f$; in which case therefore the focus is always on the other side of the glass.

And if the rays be parallel, as coming from an infinite distance, or nearly so, then will d be negative, as well as the terms in the theorem in which it is found; and therefore the other term prR will be nothing, in respect to those infinite terms; and by omitting it, the theorem will be $\frac{pdR}{dr + dr} = \frac{prR}{r + R} = f$, or $\frac{2rR}{r + R} = f$ for glass.

And here if $r = R$, or the two sides of the glass be of equal convexity, this last will become barely $\frac{2r^2}{2r}$ or only $r = f$ the focus, which therefore is in the centre of the convexity of the lens.

If the lens be a meniscus of glass; then, making r negative, the theorem is

$$\frac{-2drR}{dr + dr + 2rR} \text{ or } \frac{2drR}{dr - dr - 2rR} = f \text{ for diverging rays,}$$

$$\frac{-2drR}{dr - dr - 2rR} \text{ or } \frac{2drR}{dr - dr + 2rR} = f \text{ for converging rays,}$$

$$\text{and } \frac{-2rR}{r + R} \text{ or } \frac{2rR}{r - R} = f \text{ for parallel rays.}$$

If the lens be a double concave glass, r and R will be both negative, and then the theorem becomes

$$\frac{-2drR}{dr + dr + 2rR} = f \text{ for diverging rays, always negative;}$$

$$\frac{-2drR}{dr + dr - 2rR} = f \text{ for converging rays;}$$

$$\text{and } \frac{-2rR}{r + R} = f \text{ for parallel rays.}$$

And here, if the radii of curvature r and R be equal, this last will be barely $-r = f$ for parallel rays falling on a double concave glass of equal curvature.

Lastly, when the lens is a plano-convex glass; then, r being infinite, the theorem becomes

$$\frac{2dR}{d - 2R} = f \text{ for diverging rays,}$$

$$\frac{2dR}{d + 2R} = f \text{ for converging rays,}$$

$$\text{and } 2R = f \text{ for parallel rays.}$$

The theorems for parallel rays, as coming from an infinite distance, take place in the common refracting telescopes. And those for converging rays are chiefly of use to determine the focus resulting from any sort of lens placed in a telescope, between the focus of the object-glass and the glass itself; the distance between the said focus of the object-glass and the interposed lens being made $= d$; while those for diverging rays are chiefly of use in microscopes, reading-glasses, and other cases in which near objects are viewed.

It is evident that the foregoing general theorem will serve to find any of the other circumstances, as well as the focus, by considering this as given. Thus, for instance, suppose it be required to find the distance at which an object being placed, it shall by a given lens be represented as large as the object itself; which is of singular use in viewing and drawing them, by transmitting the image through a glass in a dark room, as in the camera obscura, which gives not only the true figure and shades, but the colours themselves as vivid as the life. Now in this case d is $= f$, which makes the theorem become $pdR = d^2r + d^2R - pdR$, and this gives $d = \frac{2prR}{r + R}$. But if the two convexities belong to equal spheres, so as that $r = R$, then it is $d = pr$, or $= 2r$ when the lens is glass. So that if the object be placed at the diameter of the sphere distant from the lens, then the focus will be as far distant on the other side, and the image as large as the object. But if the glass were a plano-convex, the same distance would be just twice as much.

Again, recurring to the first general theorem, including the thickness of the lens; let the lens be a whole sphere; then $t = 2r$, and $r = R$; and hence the theorem reduces to $\frac{pdR - 2ndr - 2npr^2}{2nd + 2nr - mpr} = f$.

And here if d be infinite, the theorem contracts to $\frac{mp - 2n}{2n} r$ or $\frac{2n - m}{2m - 2n} r = f$; or for glass $\frac{4r}{3} = f$: showing that a sphere of glass collects the sun's rays at half the radius of the sphere without it. And for a sphere of water, the focus is at the distance of a whole radius.

For another example; when a hemisphere is exposed to parallel rays; then d and R being infinite, and $t = r$, the theorem becomes $\frac{mp - n}{m} r = \frac{mn}{m^2 - mn} r = f$. That is, in glass it is $\frac{2}{3}r$, and in water $\frac{2}{4}r$.

Several other corollaries may be deduced from the foregoing principles. As follows:

1st. That the thickness of the lens, being very small, the focus will remain the same, when either side is exposed to the rays.

2d. If a luminous body be placed in a focus behind a lens, whether plano-convex, or convex on both sides; or whether equally or unequally so; the rays become parallel after refraction, as the refracted rays become what were before the incident rays. And hence, by means of a convex lens, or a little glass bubble full of water, a very intense light may be projected to a great distance. Which furnishes us with the structure of a lamp or lantern, to throw an intense light to an immense distance: for a lens, convex on both sides, being placed opposite to a concave mirror, and a lighted candle or wick being placed in the common focus of both, the rays reflected back from the mirror to the lens will be parallel to each other; and after refraction will converge, till they concur at the dis-

tance of the radius, after which they will again diverge. But the candle being likewise in the focus of the lens, the rays it throws on the lens will be parallel; and therefore a very intense light meeting with another equally intense, at the distance of the diameter from the lens, the light will be surprising: and though it afterwards decrease, yet the parallel and diverging rays going a long way together, it will be very great at a great distance. Lanterns of this kind are of considerable service in the night time, to discover remote objects.

If it be required to have the light, at the same time, transmitted to several places, as through several streets, &c, the number of lenses and mirrors must be increased.

3. The images of objects are shown inverted in the focus of a convex lens: nor is the focus of the sun's rays any thing else, in effect, but the image of the sun inverted. Hence, in solar eclipses, the sun's image, eclipsed as it is, may be burnt by a large lens on a board, &c, and exhibit a very entertaining phenomenon.

4th. If a concave mirror be so placed, as that an inverted image, formed by refraction through a lens, be found between the centre and the focus, or even beyond the centre, it will again be inverted by reflection, and so appear erect; in the first case beyond the centre, and in the latter between the centre and the focus. And on these principles the camera obscura is constructed.

5th. The image of an object, delineated beyond a convex lens, is of the same magnitude, as it would be of, were the object to shine into a dark room through a small hole, upon a wall, at the same distance from the hole, as the focus is from the lens.—When an object is less distant from a lens than the focus of parallel rays, the distance of the image is greater than that of the object; otherwise, the distance of the image is less than that of the object: in the former case therefore, the image is larger than the object; in the latter, it is less.

When the images are less than the objects, they appear more distinct and vivid; because then more rays are accumulated into a given space. But if the images be made greater than the objects, they will not appear distinctly; because in that case there are fewer rays which meet after refraction in the same point; whence it happens, that rays proceeding from different points of an object, terminate in the same point of an image, which is the cause of confusion. Hence it appears that the same aperture of a lens may be admitted in every case, if we would keep off the rays which produce confusion. However, though the image be then more distinct, when no rays are admitted but those near the axis, yet for want of rays the image is apt to be dim.

6. If the eye be placed in the focus of a convex lens, an object viewed through it, appears erect, and enlarged in the ratio of the distance of the object from the eye, to that of the eye from the lens, if it be near; but infinitely if remote.

7th. An object viewed through a concave lens, appears erect, and diminished in a ratio compounded of the ratios of the space in the axis between the point of incidence, and the point to which an oblique ray would pass without refraction, to the space in the axis between the eye and the middle of the object; and the space in the same axis between the eye and the point of incidence, to the space between the middle of the object and the point to which the oblique ray would pass without refraction.

Finally, it may be observed, that the very small magnifying glasses used in microscopes, most properly come un-

der the denomination of lens, as they most approach to the figure of the lentil, a seed of the vetch or pea kind, from whence the name is derived; but the reading glasses, and burning glasses, and all that magnify, come under the same denomination; for their surfaces are convex, though less so. A drop of water is a lens, and it will serve as one; and many have used it by way of lens in their microscopes. A drop of any transparent fluid, enclosed between two concave glasses, acquires the shape of a lens, and has all its properties. The crystalline humour of the eye is a lens exactly of this kind; it is a small quantity of a translucent fluid, contained between two concave and transparent membranes, called the coats of the eye; and it acts as the lens made of water would do, in an equal degree of convexity.

LEO, the Lion, a considerable constellation of the northern hemisphere, being one of the 48 old constellations, and the 5th sign of the zodiac. It is marked thus , as a rude sketch of the animal. The Greeks fabled that this was the Nemean lion, which had dropped from the moon, but being slain by Hercules, was raised to the heavens by Jupiter, in commemoration of the dreadful conflict, and in honour of that hero. But the hieroglyphical meaning of this sign, so depicted by the Egyptians long before the invention of the fables of Hercules, was probably no more than to signify, by the fury of the lion, the violent heats occasioned by the sun when he entered that part of the ecliptic.—The stars in the constellation Leo, in Ptolemy's catalogue are 27, besides 8 unformed ones, now counted in the constellation Coma Berenices; in Tycho's 30, in that of Hevelius 49, and in Flamsteed's 95; one of them, of the first magnitude, in the breast of the Lion, is called Regulus, and *Cor Leonis*, or Lion's Heart.

LEO MINOR, the Little Lion, a constellation of the northern hemisphere, and one of the new ones that were formed out of what were left by the ancients, under the name of stellæ informes, or unformed stars, and added to the 48 old ones. It contains 53 stars in Flamsteed's catalogue.

Cor Leonis, Lion's heart, a fixed star, of the first magnitude, in the sign leo; called also regulus, basilicus, &c.

LEPUS, the Hare, a constellation of the southern hemisphere, and one of the 48 old constellations. The Greeks fabled, that this animal was placed in the heavens, near Orion, as being one of the animals which he hunted. But it is probable their masters, the Egyptians, had some other meaning in this hieroglyphic. The stars in the constellation lepus, in Ptolemy's catalogue are 12, in Tycho's 13, and in Flamsteed's 19.

LEUCIPPUS, a celebrated Greek philosopher and mathematician, who flourished about the 428th year before Christ. He was the first author of the famous system of atoms and vacuums, and of the hypothesis of storms; since attributed to the moderns.

LEVEL, an instrument used to make a line parallel to the horizon, and to continue it out at pleasure; and by this means to find the true level, or the difference of ascent or descent between two or more places, for conveying water, draining fens, &c. There are several instruments, of different constructions and materials invented for the perfection of levelling, as may be seen in Lahire's and Picard's treatises of levelling, in Biron's treatise on mathematical instruments, as also in the Philos. Trans. and the Mémoires de l'Acad. &c. But they may be reduced to the following kinds.

Water-LEVEL, that which shows the horizontal line by means of a surface of water or other fluid; founded on this principle, that water always places itself level or horizontal. The most simple kind is made of a long wooden trough or canal; which being equally filled with water, its surface shows the line of level. And this is the chrobarotes of the ancients, described by Vitruvius, lib. viii, cap. 6. The water-level is also made with two cups fitted to the two ends of a straight tube, about an inch diameter, and 3 or 4 feet long, by means of which the water communicates from the one cup to the other; and this pipe being moveable on its stand by means of a ball and socket, when the two cups show equally full of water, their two surfaces mark the line of level.

This instrument, instead of cups, may also be made with two short cylinders of glass 3 or 4 inches long, fastened to each extremity of the pipe with wax or mastic. The pipe is filled with common or coloured water, which shows itself through the cylinders, by means of which the line of level is determined; the height of the water, with respect to the centre of the earth, being always the same in both cylinders. This level, though very simple, is however very commodious for levelling small distances. See the method of preparing and using a water-level, and a mercurial level, annexed to Davis's quadrant, for the same purpose, by Mr. Leigh, in Philos. Trans. vol. xl. 417, or my Abr. viii, 260.

Air-LEVEL, is that which shows the line of level by means of a bubble of air, enclosed with some fluid in a glass tube, of an indeterminate-length and thickness, and having its two ends hermetically sealed: an invention, it is said, of M. Thevenot. When the bubble fixes itself at a certain mark, made exactly in the middle of the tube, the case or ruler in which it is fixed, is then level; and when it is not level, the bubble will rise to one end. This glass-tube may be set in another of brass, having an aperture in the middle, where the bubble of air may be observed. The liquor with which the tube is filled, is usually either oil of tartar, or aqua secunda; those not being liable to freeze as common water, nor to rarefaction and condensation as spirit of wine is.

There is one of these instruments with sights, being an improvement on that last described, which, by the addition of other apparatus, becomes more exact and commodious. It consists of an air-level, No. 1, (fig. 1, pl. 18) about 8 inches long, and about two thirds of an inch in diameter, set in a brass tube, 2, having an aperture in the middle c. The tubes are carried in a strong straight ruler, of a foot long; at the ends of which are fixed two sights, 3, 3, exactly perpendicular to the tubes, and of an equal height, having a square hole, formed by two fillets of brass crossing each other at right angles; in the middle of which is drilled a very small hole, through which a point on a level with the instrument is seen. The brass tube is fastened to the ruler by means of two screws; the one of which, marked 4, serves to raise or depress the tube at pleasure, for bringing it towards a level; the top of the ball and socket is riveted to a small ruler that springs, one end of which is fastened with springs to the great ruler, and at the other end is a screw, 5, serving to raise and depress the instrument when nearly level. But this instrument is less commodious than the following one: for though the holes be ever so small, yet they will still take in too great a space to determine the point of level precisely.

Fig. 2, is a *Level with Telescopic Sights*, first invented by

Mr. Huygens. It is like the last; with only this difference, that instead of plain sights, it carries a telescope, to determine exactly a point of level at a considerable distance. The screw 3, is for raising or lowering a little fork, which carries the hair, and making it agree with the bubble of air when the instrument is level; and the screw 4, is for making the bubble of air, d or e, agree with the telescope. The whole is fitted to a ball and socket, or otherwise moved by joints and screws.—It may be observed that a telescope may be added to any kind of level, by applying it upon, or parallel to, the base or ruler, when there is occasion to take the level of remote objects: and it possesses this advantage, that it may be inverted by turning the ruler and telescope half round; and if then the hair cut the same point that it did before, the operation is just. Many varieties and improvements of this instrument have been made by the more modern opticians.

Dr. Desaguliers proposed a machine for taking the difference of level, which contained the principles both of a barometer and thermometer; but it is not accurate in practice: Philos. Trans. vol. xxxiii, pa. 165, or my Abr. vol. vii, 49. Fig. 3, 4, 5, 6.

Mr. Hadley too has contrived a Spirit Level to be fixed to a quadrant, for taking a meridian altitude at sea, when the horizon is not visible. See the description and figure of it in the Philos. Trans. vol. xxxviii, 167, or Abr. vii, 620. Various other spirit levels, and mercurial levels, are also invented and used on different occasions.

Reflecting LEVEL, that made by means of a pretty long surface of water, representing the same object inverted, which we see erect by the eye; so that the point where these two objects appear to meet, is on a level with the place where the surface of the water is found. This is the invention of M. Mariotte.

There is another reflecting level, consisting of a polished metal mirror, placed a little before the object glass of a telescope, suspended perpendicularly. This mirror must be set at an angle of 45 degrees; in which case the perpendicular line of the telescope becomes a horizontal line, or a line of level. Which is the invention of M. Cassini.

Artillery Foot-LEVEL, is in form of a square (fig. 7), having its two legs or branches of an equal length; at the junction of which is a small hole, by which hangs a plummet playing on a perpendicular line in the middle of a quadrant, which is divided both ways from that point into 45 degrees. This instrument may be used on other occasions, by placing the ends of its two branches on a plane; for when the plummet plays perpendicularly over the middle division of the quadrant, the plane is then level. To use it in gunnery, place the two ends on the piece of artillery, which may be raised to any proposed height, and the plummet will cut the degree above the level. But this supposes the outside of the cannon is parallel to its axis, which is not always the case; and therefore another instrument is employed either to set the piece level, or elevate it at any angle: namely a small quadrant, with one of its radii continued out pretty long, which being put into the inside of the cylindrical bore, the plummet shows the angle of elevation, or the line of level. See *Gunner's QUADRANT*.

Carpenter's, Bricklayer's, or Pavior's LEVEL, consists of a long ruler, in the middle of which is fitted at right angles another broader piece, at the top of which is fastened a plummet, which when it hangs over the middle line of the

2d or upright piece, shows that the base or long ruler is horizontal or level. Fig. 8.

Mason's LEVEL, is composed of 3 rules, so jointed as to form an isosceles triangle, somewhat like a Roman A; from the vertex of which is suspended a plummet, which hangs directly over a mark in the middle of the base, when this is horizontal or level. Fig. 8.

Plumb or Pendulum LEVEL, said to be invented by M. Picard; fig. 10. This shows the horizontal line by means of another line perpendicular to that described by a plummet or pendulum. It consists of two legs or branches, joined at right angles, the one of which, of about 18 inches long, carries a thread and plummet; the thread being hung near the top of the branch, at the point 2. The middle of the branch where the thread passes is hollow, so that it may hang free every-where: but towards the bottom, where there is a small blade of silver, on which a line is drawn perpendicular to the telescope, the said cavity is covered by two pieces of brass, with a piece of glass o, to see the plummet through, forming a kind of case, to prevent the wind from agitating the thread. The telescope, of a proper length, is fixed to the other leg of the instrument, at right angles to the perpendicular, and having a hair stretched horizontally across the focus of the object-glass, which determines the point of level, when the string of the plummet hangs against the line on the silver blade: the whole being fixed by a ball and socket to its stand.

Fig. 12, is a *Balance LEVEL*; which being suspended by the ring, the two sights, when in equilibrio, will be horizontal, or in a level.

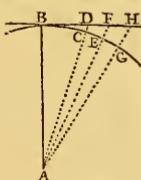

Some other levels are also represented in pl. 18.

LEVELLING, the art or act of finding a line parallel to the horizon v.t one or more stations, to determine the height or depth of one place with respect to another; for laying out grounds even, regulating descents, draining morasses, conducting water, &c.

Two or more places are on a true level when they are equally distant from the centre of the earth. Also one place is higher than another, or out of level with it, when it is farther from the centre of the earth: and a line equally distant from that centre in all its points, is called the line of True Level. Hence, because the earth is round, that line must be a curve, and make a part of the earth's circumference, or at least parallel to it, or concentrical with it; as the line *EE'GG'*, which has all its points equally distant from the centre of the earth; considering it as a perfect globe.

But at the line of sight *BDF&c*, given by the operations of levels, is a tangent *t*, or a right line perpendicular to the semidiameter of the earth at the point of contact *B*; rising always higher above the true line of level, the farther the distance is, this being called the Apparent Line of Level. Thus, *CD* is the height of the apparent level above the true level, at the distance *BC* or *BD*; also *EF* is the excess of height at *E*; and *GH* at *G*; &c. The difference, it is evident, is always equal to the excess of the secant of the arch of distance above the radius of the earth.

The common methods of levelling are sufficient for laying pavements of walks, or for conveying water to small distances, &c: but in more extensive operations, as in

levelling the bottoms of canals, which are to convey water to the distance of many miles, and such like, the difference between the true and the apparent level must be taken into the account.

Now the difference *CD* between the true and apparent level, at any distance *BC* or *BD*, may be found thus: By a well-known property of the circle $2AC + CD : BD :: BD : CD$; or because the diameter of the earth is so great with respect to the line *CD* at all distances to which an operation of levelling commonly extends, that $2AC + CD$ may be safely taken for $2AC + CD$ in that proportion without any sensible error, it will be $2AC : BD :: BD : CD$, which therefore is $= \frac{BD^2}{2AC}$ or $\frac{BC^2}{2AC}$ nearly; that is, the difference between the true and apparent level, is equal to the square of the distance between the places, divided by the diameter of the earth; and consequently it is always proportional to the square of the distance.

Now the diameter of the earth being nearly 7914 miles; if we first take $BC = 1$ mile, then the excess $\frac{BC^2}{2AC}$ becomes

$\frac{1}{7914}$ of a mile, which is 8 inches, the height of the apparent above the true level at the distance of one mile. Hence, proportioning the excesses in altitude according to the squares of the distances, the following table is obtained, which shows the height of the apparent above the true level for every 100 yards of distance on the one hand, and for every mile on the other.

Dist. or BC.	Dif. of level, or CD.	Dist. or BC.	Dif. of level, or CD.
Yards.	Inches.	Miles.	Feet. Inches.
100	0'026	$\frac{1}{5}$	0 0 $\frac{1}{2}$
200	0'103	$\frac{1}{2}$	0 2
300	0'231	$\frac{3}{4}$	0 4 $\frac{1}{2}$
400	0'411	1	0 8
500	0'643	2	2 8
600	0'925	3	6 0
700	1'260	4	10 7
800	1'654	5	16 7
900	2'081	6	23 11
1000	2'570	7	32 6
1100	3'110	8	42 6
1200	3'701	9	53 9
1300	4'344	10	66 4
1400	5'038	11	80 3
1500	5'784	12	95 7
1600	6'580	13	112 2
1700	7'425	14	130 1

By means of these tables of reductions, we can now level to almost any distance at one operation, which the ancients could not do but by a great multitude; for, being unacquainted with the correction answering to particular distances, they only levelled from one 20 yards to another, where they had occasion to continue the work to any considerable extent.

This table will answer several useful purposes. Thus, first, to find the height of the apparent above the true level, at any distance. If the given distance be contained in the table, the correction of level is found on the same line with it: thus at the distance of 1000 yards, the correction is 2'57, or two inches and a half nearly; and at the distance of 10 miles, it is 66 feet 4 inches. But if

the exact distance be not found in the table, then multiply the square of the distance in yards by 2·57, and divide by 1,000,000, or cut off 6 places on the right for decimals, and the rest will be inches : or multiply the square of the distance in miles by 66 feet 4 inches, and divide by 100. 2ndly, To find the extent of the visible horizon, or how far can be seen from any given height, on a horizontal plane, as at sea, &c: Suppose the eye of an observer, on the top of a ship's mast at sea, be at the height of 130 feet above the water, he will then see about 14 miles all around. Or from the top of a cliff by the sea-side, the height of which is 66 feet, a person may see to the distance of near 10 miles on the surface of the sea. Also, when the top of a hill, or the light in a lighthouse, or such like, whose height is 130 feet, first comes into the view of an eye on board a ship; the table shows that the distance of the ship from it is 14 miles, if the eye be at the surface of the water; but if the height of the eye in the ship be 80 feet, then the distance will be increased by near 11 miles, making in all about 25 miles, distance.

3dly, Suppose a spring to be on one side of a hill, and a house on an opposite hill, with a valley between them; and that the spring seen from the house appears, by a levelling instrument, to be on a level with the foundation of the house, which suppose is at a mile distance from it; then is the spring 8 inches above the true level of the house; and this difference would be about sufficient for the water to be brought in pipes from the spring to the house.

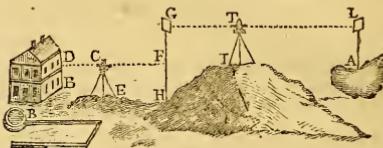

4th, If the height or distance exceed the limits of the table: Then, first, if the distance be given, divide it by 2, or by 3, or by 4, &c, till the quotient come within the distances in the table; then take out the height answering to the quotient, and multiply it by the square of the divisor, that is by 4, or 9, or 16, &c, for the height required: So, if the top of a hill be just seen at the distance of 40 miles; then 40 divided by 4 gives 10, to which in the table answers $60\frac{1}{2}$ feet, which being multiplied by 16, the square of 4, gives $1061\frac{1}{2}$ feet for the height of the hill. But when the height is given, divide it by one of these square numbers 4, 9, 16, 25, &c, till the quotient come within the limits of the table, and multiply the quotient by the square root of the divisor, that is by 2, or 3, or 4, or 5, &c, for the distance sought: So when the top of the peak of Teneriff, said to be almost 3 miles or 15,840 feet high, just comes into view at sea; divide 15,840 by 225, or the square of 15, and the quotient is 70 nearly; which answers in the table, by proportion, to about $10\frac{1}{2}$ miles; then multiplying $10\frac{1}{2}$ by 15, gives $154\frac{1}{2}$ miles, for the distance of the hill.

On the Practice of Levelling.

The operation of levelling is as follows. Suppose the height of the point A on the top of a mountain, above that of B, at the foot of it, to be required. Place the level about the middle distance at D, and set up pickets, poles, or staffs, at A and B, where persons must attend with signals for raising and lowering, on the said poles, little marks of paste-board or other matter. The level having been placed horizontally by the bubble, &c, look towards the staff AE, and cause the person

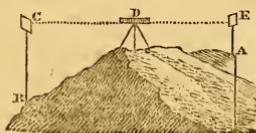

there to raise or lower the mark, till it appear through the telescope, or sights, &c, at E: then measure exactly the perpendicular height of the point A above the point B, which suppose 5 feet 8 inches, set it down in your book. Then direct your sight the other way, towards the pole B, and cause the person there to raise or lower his mark, till it appear in the visual line as before at C; and measuring the height of C above B, which suppose 15 feet 6 inches; set this down in your book also, immediately above the number of the first observation. Then subtract the one from the other, and the remainder 9 feet 10 inches, will be the difference of level between A and B, or the height of the point A above the point B.

If the point D, where the instrument is fixed, be exactly in the middle between the points A and B, there will be no necessity for reducing the apparent level to the true one, the visual ray on both sides being raised equally above the true level. But if not, each height must be corrected or reduced according to its distance, before the one corrected height is subtracted from the other; as in the case following.

When the distance is very considerable, or irregular, so that the operation cannot be effected at once placing of the level; or when it is required to know if there be a sufficient descent for conveying water from the spring A to the point B; it will be necessary to perform this at several operations. Having chosen a proper place for the first station, as at 1, fix a pole at the point A near the spring, with a proper mark to slide up and down it, as L; and measure the distance from A to 1. Now the level being adjusted in the point 1, let the mark L be raised or lowered till it is seen through the telescope or sights of the level, and measure the height AL. Then having fixed another pole at II, direct the level to it, and cause the mark G to be moved up or down till it appear through the instrument: then measure the height GH, and the distance from 1 to II; noting them down in the book. This done, remove the level forwards to some other eminence as E, from which the pole II may be viewed, as also another pole at D; and having adjusted the level in the point E, look back to the pole II; managing the mark as before, till the visual ray will give the point F; then measuring the distance HE and the height HF, note them down in the book. And here turn the level to look at the next pole D, and the visual ray will give the point B; there measure the height of D, and the distance EB, entering them in the book as before. And thus proceed from one station to another, till the whole is completed.

But all these heights must be corrected or reduced by the foregoing table, according to their respective distances; and the whole, both distances and heights, with their corrections, entered in the book in the following manner.

Back-sights.			Fore-sights.		
Dists.	Hts.	Cors.	Dists.	Hts.	Cors.
yds.	ft.	in.	yds.	ft.	in.
AL 1650	11	3	III 1265	19	5
HF 910	10	7	EB 900	8	1
2590	21	10	2165	27	6
		9'2			6'1
	21	0'8		26	11'9
				21	0'8
				Whole Dif. of	
				level	5 11'1

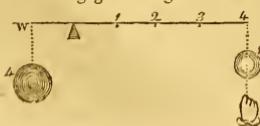

Having summed up all the columns, add those of the distances together, and the whole distance from A to B is 4755 yards, or 2 miles and 3 quarters nearly. Then, the sums of the corrections taken from the sums of the apparent heights, leave the two corrected heights; the one of which being taken from the other, leaves 5 feet 11'1 inc. for the true difference of level sought between the two places A and B, which is at the rate of an inch and half nearly to every 100 yards, a quantity more than sufficient to cause the water to run from the spring to the house.

Or, the operation may be otherwise performed, thus: Instead of placing the level between every two poles, and taking both back-sights and fore-sights; plant it first at the spring A, and thence observe the level to the first pole; then remove it to this pole, and observe the 2d pole; next move it to the 2d pole, and observe the 3d pole; and so on, from one pole to another, always taking forward sights or observations only. Then at the last, add all the corrected heights together, and the sum will be the whole difference of level sought.

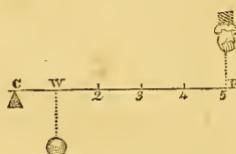

Dr. Halley suggested a new method of levelling, performed wholly by means of the barometer, the mercury being suspended at so much the less height, as the place is farther remote from the centre of the earth; and hence the different heights of the mercury in two places, give the difference of level. This method is, in fact, no other than the method of measuring altitudes by the barometer, which has lately been so successfully practised and perfected by M. Deluc and others; but though it serves very well for the heights of hills, and other considerable altitudes, it is not accurate enough for determining small altitudes, to inches and parts. See the Barometrical Measurement of Altitudes.

LEVELLING Poles, or Staves, are instruments used in levelling, for carrying the marks to be observed, and at the same time to measure the heights of those marks from the ground. They usually consist each of two long wooden rulers, made to slide over each other, and divided into feet and inches, &c.

LEVER, a straight bar of iron or wood, &c, supposed to be inflexible, supported on a fulcrum or prop by a single point, about which all the parts are moveable. The lever is the first of those simple machines called mechanical powers, being the simplest of them all; and is chiefly used for raising great weights to small heights.

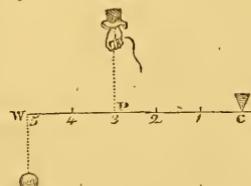

The lever is of three kinds. First the common sort, where the weight intended to be raised is at one end of it, our strength or another weight called the power is at the other end, and the prop or fulcrum is between them both. In stirring up the fire with poker, we make use of this lever; the poker is the lever, it rests on one of the bars of the grate as a prop, the incumbent fuel is the weight to be overcome, and the pressure of the hand on the other end is the force or power. In this, as in all the other machines, we have only to increase the distance between the force and the prop, or to decrease the distance between the weight and the prop, to give the operator the greater power or effect. To this kind of lever may also be referred all scissars, pincers, snuffers, &c. The steel-yard and the common balance are also levers of this kind.

In the lever of the 2d kind the prop is at one end, the force or power at the other, and the weight to be raised is between them. Thus, in raising a water-plug in the streets, the workman puts his iron bar or lever through the ring or hole of the plug, till the end of it reaches the ground on the other side; then making that the prop, he lifts the plug by his force or strength applied at the other end of the lever. In this lever too, the nearer the weight is to the prop, or the farther the power from the prop, the greater is the effect. To this 2d kind of lever may also be referred the oars and rudder of a boat, the masts of a ship, cutting knives fixed at one end, and doors, whose hinges serve as a fulcrum.

In the lever of the third kind, the power acts between the weight and the prop; such as a ladder raised by a man somewhere between the two ends, to rear it against a wall, or a pair of tongs, &c.

It is by this kind of lever also that the muscular motions of animals are performed, the muscles being inserted much nearer to the centre of motion, than the point where is placed the centre of gravity of the weight to be raised; so that the power of the muscle is many times greater than the weight it is able to sustain. And in this third kind of lever, to produce a balance between the power and weight, the power or force must exceed the weight, in the same proportion as it is nearer the prop than the weight is; whereas, in the other two kinds, the power is less than the weight, in the same proportion as its distance is greater; that is, universally, the power and weight are

each of them reciprocally as their distance from the prop; as is demonstrated below.

Some authors make a 4th kind, of what is called a bended lever; such as a hammer in drawing a nail, &c.

In all levers, the universal property is, that the effect of either the weight or the power, to turn the lever about the fulcrum, is directly as its force and its distance from the prop, that is as df , where d denotes the distance, and f the force, strength, or weight, &c, of the agent. For since it is proved that at a double distance it will have a double effect, at a triple distance a triple effect, and so on; also since a double force produces a double effect, a triple force a triple effect, and so on; therefore universally the effect is as df the product of the two. In like manner, if p be the distance of another power or agent, whose intensity is r , then is dr the effect of this also to move the lever. And if these two agents act against each other on the lever, and their effects be supposed equal, or the lever kept in equilibrio by the equal and contrary effects of these two agents; then is $dr = df$, which equation resolves into this analogy, viz, $p : d :: f : r$; that is, the distances of the agents from the prop, are reciprocally or inversely as their forces, or the power is to the weight, as the distance of the latter from the prop is to the distance of the former.

Writers on mechanics commonly demonstrate this proportion in a very absurd manner, viz, by supposing the lever put into motion about the prop, and then inferring that, because the momenta of two bodies are equal, when placed upon the lever at such distances, that these distances are reciprocally proportional to the weights of the bodies, and that therefore this is also the proportion in case of an equilibrium; which is an attempt absurdly to demonstrate a thing, supposing the contrary, that a body is at rest, by supposing it to be in motion. I shall therefore give here a universal demonstration of the property, on the pure principles of rest and pressure, or force only. Thus, let rw be a lever, c the prop, and p and w any two forces acting on the lever at the points r and w , in the directions rp , rw ; then if ce and cd be the perpendicular distances of the directions of these forces from the prop c , it is to be demonstrated that $p : w :: cd : ce$. In order to which join co , and draw cb parallel to wo , and cr parallel to ro . Then will co , the perpendicular to rw , be the direction of the pressure on the prop, otherwise there could be no equilibrium, for the directions of three forces that keep each other in equilibrium, must necessarily meet in the same point. And because any three forces that keep each other in equilibrium, are proportional to the three sides of a triangle formed by drawing lines parallel to the directions of these forces; therefore the forces on p , c , and w , are as the three lines bo , co , cb , which are in the same direction, or parallel to them; that is, the force p is to the force w , as bo is to ce ; and the force p is to the force w , as bo is to ce ; that is to cb . But the two triangles cde , cbe are equiangular, and have their like sides proportional,

$$\text{viz}, ce : cf : cb :: cd : ce;$$

and because it was $cf : cb :: p : w$; therefore by equality $p : w :: cd : ce$; that is, each force is reciprocally proportional to the distance of its direction from the fulcrum. And it will be

found that this demonstration serves also for the other kinds of levers, by drawing the lines as directed. Hence, if any given force p be applied to a lever at a ; its effect upon the lever, to turn it about the centre of motion c , is as the length of the arm ca , and the sine of the angle of direction cae . For the perp. ce is as $ca \times \sin. \angle a$.

It having been objected to the principle of this demonstration, that it inferred the stability of the lever, or the line rw , from the theorem that three forces meeting in a point, and keeping that point, or a body there, stable or fixed, are proportional to the three sides of a triangle which are parallel to their directions; which is a misconception. For, it is only meant that the point o is stable by that theorem. As to the stability of the lever rw , that is inferred from its being perp. to the given line oc , and limited by the two lines op , ow , given in position.—Since the time when the above demonstration was printed in the first edition of this Dictionary, I have seen another similar one that had been given in Dr. Hamilton's Essays.

In any analogy, because the product of the extremes is equal to that of the means; therefore the product of the power by the distance of its direction is equal to the product of the weight by the distance of its direction. That is, $p \times ce = w \times cd$.

If the lever, with the two weights fixed to it, be made to move about the centre c ; the momentum of the power will be equal to that of the weight; and the weights will be reciprocally proportional to their velocities.

When the two forces act perpendicularly on the lever, as two weights &c; then, in case of an equilibrium, \mathbf{E}

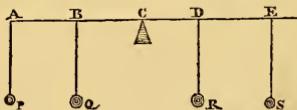

coincides with p , and d with w ; and the distances cp , cw , taken on the lever, or the distances of the power and weight, from the fulcrum, are reciprocally proportional to the power and weight.

In a straight lever, when kept in equilibrio by a weight and power acting perpendicularly upon it; then, of these three, the power, weight, and pressure on the prop, any one is as the distance of the other two.

And hence too $p + w : p :: ED : CD$,
and $p + w : w :: ED : CP$;

that is, the sum of the weights is to either of them, as the sum of their distances is to the distance of the other.

Also, if several weights p , q , r , s , &c, act on a straight lever, and keep it in equilibrio; then the sum of the products on one side of the prop, will be equal to the sum on the other side, made by multiplying each weight by its distance from the prop; viz, $p \cdot AC + q \cdot BC = R \cdot DC + s \cdot EC + \&c.$

Hitherto the lever has been considered as a mathematical line void of weight or gravity. But when its weight is considered, it is to be done thus: Find the weight and the centre of gravity of the lever alone, and then consider it as a mathematical line, but having an equal weight suspended by that centre of gravity; and so combine its effect with those of the other weights, as above.

On the foregoing principles depends the nature of scales and beams for weighing all bodies. For, if the distances be equal, then will the weights be equal also; which gives the construction of the common scales. And the Roman statera, or steel-yard, is also a lever, but of unequal arms or distances, so contrived that one weight only may suffice to weigh a great many, by sliding it backwards and forwards to different distances upon the longer arm of the lever. See BALANCE, &c.

Also, on the principle of the lever depend almost all other mechanical powers and effects. See WHEEL-AND-AXLE, PULLEY, WEDGE, SCREW, &c.

LEVITY, the privation or want of weight in any body, when compared with another that is heavier; in which sense it stands opposed to gravity. Thus cork, and most sorts of wood that float in water, have levity with respect to water, that is, are less heavy. The schools maintained that there was such a thing as positive and absolute levity; and to this they imputed the rise and buoyancy of bodies lighter in specie than the bodies in which they rise and float. But it is now well known that this happens only in consequence of the heavier and denser fluid, which, by its superior gravity, gains the lowest place, and raises up the lighter body by a force which is equal to the difference of their gravities. It was demonstrated by Archimedes, that a solid body will float any-where in a fluid of the same specific gravity as itself; and that a lighter body will always be raised up in it.

LEUWENHOEK (ANTONY), a celebrated Dutch philosopher, was born at Delft in 1632; and acquired a great reputation throughout all Europe, by his experiments and discoveries in natural history, by means of the microscope. He particularly excelled in making glasses for microscopes and spectacles; and he was a member of most of the literary societies of Europe; to whom he sent many memoirs. Those in the Philosophical Transactions, and in the Paris Memoirs, extend through many volumes; the former were extracted, and published at Leyden, in 1722. He died in 1723, at 91 years of age.

LEYBOURN (WILLIAM), a respectable and very useful mathematician, of the 17th century, died about the year 1690. He was, it seems, originally a printer in London; but by industry became a considerable proficient in mathematics, and published a number of very useful and popular books. on the practical parts of those sciences. Those of them that are in my possession, are the following: 1. Compleat Surveyor, in folio, 1653, afterwards re-published and improved by Cunn.—2. Nine Geometrical Exercises, in 4to, 1669.—3. Dialling, in 4to, 1687; the same in folio, 1700.—4. Cursus Mathematicus, 2 vols folio, 1690, then held in much esteem.—5. Recreations, in folio, 1694.—6. Arithmetic, 8vo, 1700.—7. On the Gunter's Quadrant, 12mo, 1731. There may be other editions of these works, and probably earlier ones of several of them, as well as of other works which I have not seen, such as one entitled the Trader's Guide.

LEYDEN PHIAL, in Electricity, is a glass phial or jar, coated both within and without with tin-foil, or some other conducting substance, that it may be charged, and thus employed in a variety of useful and entertaining experiments. Or even flat glass, or any other shape, so coated and used, has also received the same denomination. Also a vacuum produced in such a jar, &c, has been named the Leyden Vacuum.

The Leyden phial has been so called, because it is said that M. Cunaeus, a native of Leyden, first contrived, about the close of the year 1745, to accumulate the electrical power in glass, and to use it in the same manner as at present. But Dr. Priestley asserts that this discovery was first made by Von Kleist, dean of the cathedral in Camin; who, on the 4th of November 1745, sent an account of it to Dr. Lieberkuhn at Berlin: however, those to whom Kleist's account was communicated, could not succeed in performing his experiments. The chief circumstances of this discovery are stated by Dr. Priestley in his Hist. of Electricity, vol. 1, pa. 191, &c.

LIBRA. See BALANCE.

LIBRA is also one of the 48 old constellations, and the 7th sign of the zodiac, being opposite to Aries, and marked like a part of a pair of scales, thus . The figure of the balance was probably given to this part of the ecliptic, because when the sun arrives at this part, which is at the time of the autumnal equinox, the days and nights are equal, as if weighed in a balance. The stars in this constellation are, according to Ptolemy 17, Tycho 10, Hevelius 20, and Flamsteed 51.

LIBRA also denotes the ancient Roman pound, which was divided into 12 unciae, or ounces, and the ounce into 24 scruples. It seems the mean weight of the scruple was nearly equal to $17\frac{1}{2}$ grains Troy, and consequently the libra, or pound, equal to 5040 grains. It was also the name of a gold coin, equal in value to 20 denarii. See Philos. Trans. vol. 61, pa. 462.

The French livre is derived from the Roman libra, as this was from the Sicilians, who called it litra. This was used in France for the proportions of their coin till about the year 1100, their sols being so proportioned as that 20 of them were equal to the libra. By degrees it became a term of account, and every thing of the value of 20 sols was called a livre.

LIBRATION, of the Moon, is an apparent irregularity in her motion, by which she seems to librate, or waver, about her own axis, at one time towards the east, and at another towards the west. See MOON, and EJECTION. Hence it is that some parts, near the moon's western edge, at one time recede from the centre of the disc, while those on the other or eastern side approach nearer to it; and, on the contrary, at another time the western parts are seen to be nearer the centre, and the eastern parts farther from it: by which means it happens that some of those parts, which were before visible, set and hide themselves in the hinder or invisible side of the moon, and afterwards return and appear again, on the nearer or visible side.

This libration of the moon was first discovered by Hevelius, in the year 1654; and it is owing to her equable rotation round her own axis, once in a month, in conjunction with her unequal motion in the perimeter of her orbit round the earth. For if the moon moved in a circle, having its centre coinciding with the centre of the earth, while it turned on its axis in the precise time of its period round the earth, then the plane of the same lunar meridian would always pass through the earth, and the same face of the moon would be constantly and exactly turned towards us. But since the real motion of the moon is about a point at a considerable distance from the centre of the earth, that motion is very unequal, as seen from hence, the plane of no one meridian constantly passing through the earth.

The libration of the moon is of three kinds.

1st, Her libration in longitude, or a seeming vibrating motion according to the order of the signs of the zodiac. This libration is nothing twice in each periodical month, viz; when the moon is in her apogeeum, and when in her perigeeum; for in both these cases the plane of her meridian, which is turned towards us, is directed alike towards the earth.

2d, Her libration in latitude; which arises from hence, that her axis not being perpendicular to the plane of her orbit, but inclined to it, sometimes one of her poles, and sometimes the other will decline, as it were, or dip a little towards the earth, and consequently she will appear to librate a little, and to show sometimes more of her spots, and sometimes less of them, towards each pole; which libration, depending on the position of the moon, in respect to the nodes of her orbit, and her axis being nearly perpendicular to the plane of the ecliptic, is very properly said to be in latitude: and this also is completed in the space of the moon's periodical month, or rather while the moon is returning again to the same position, in respect of her nodes.

3d, There is also a third kind of libration; by which it happens that though another part of the moon be not really turned to the earth, as in the former libration, yet another is illuminated by the sun. For since the moon's axis is nearly perpendicular to the plane of the ecliptic, when she is most southerly, in respect of the north pole of the ecliptic, some parts near to it will be illuminated by the sun; while, on the contrary, the south pole will be in darkness. In this case therefore, if the sun be in the same line with the moon's southern limit, then, as she proceeds from conjunction with the sun towards her ascending node, she will appear to dip her northern polar parts a little into the dark hemisphere, and to raise her southern polar parts as much into the light one: and the contrary to this will happen two weeks after, while the new moon is descending from her northern limit; for then her northern polar parts will appear to emerge out of darkness, and the southern polar parts to dip into it: which seeming libration, or rather these effects of the former libration in altitude, depending on the light of the sun, will be completed in the moon's synodical month. Greg. Astron. lib. 4, sect. 10.

LIBRATION of the Earth, is a term applied by some astronomers to that motion, by which the earth is so retained in its orbit, that its axis continues constantly parallel to the axis of the world. This Copernicus calls the motion of libration, which may be thus illustrated: Suppose a globe, with its axis parallel to that of the earth, painted on a flag at the head of a mast, moveable on its axis, and constantly driven by an east wind, while it sails round an island, it is evident that the painted globe will be so librated, as that its axis will be parallel to that of the world, in every situation of the ship.

LIFE-ANNUITIES, are such periodical payments as depend on the continuance of some particular life or lives; and they may be distinguished into annuities that commence immediately, and such as commence at some future period, called reversionary life-annuities.

The value, or present worth, of an annuity for any proposed life or lives, it is evident, depends on two circumstances, the interest of money, and the chance or expectation of the continuance of life. On the former only, it has been shown, under the article *ANNUITIES*, depends the value or present worth of an annuity certain, or that is not subject to the continuance of a life, or other contingency; but the expectation of life being a thing not certain, but only possessing a certain chance, it is evident that the value of the certain annuity, as stated above, must be diminished in proportion as the expectancy is below certainty: thus, if the present value of an annuity certain be any sum, as suppose 100*l.* and the value or expectancy of the life be $\frac{1}{2}$, then the value of the life-annuity will be only half of the former, or 50*l.*; and if the value of the life be only $\frac{1}{3}$, the value of the life-annuity will be but $\frac{1}{3}$ of 100*l.* that is 33*l. 6s. 8d.* and so on.

The measure of the value or expectancy of life, depends on the proportion of the number of persons that die, out of a given number, in the time proposed; thus, if 50 persons die, out of 100, in any proposed time, then, half the number only remaining alive, any one person has an equal chance to live or die in that time, or the value of his life for that time is $\frac{1}{2}$; but if $\frac{2}{3}$ of the number die in the time proposed, or only $\frac{1}{3}$ remain alive, then the value of any one's life is $\frac{1}{3}$; and if $\frac{3}{4}$ of the number die, or only $\frac{1}{4}$ remain alive, then the value of any life is but $\frac{1}{4}$; and so on. In these proportions then must the value of the annuity certain be diminished, to give the value of the like life annuity.

It is plain therefore that, in this business, it is necessary to know the value of life at all the different ages, from some table of observations on the mortality of mankind, which may show the proportion of the persons living, out of a given number, at the end of any limited time; or from some certain hypothesis, or assumed principle. Now various tables and hypotheses of this kind have been given by the writers on this subject, as Dr. Halley, Mr. De-moivre, Mr. Thomas Simpson, Mr. Dodson, Mr. Kersseboom, Mr. Parcieux, Dr. Price, Mr. Morgan, Mr. Baron Maseres, Mr. Baily, and many others. But the same table of probabilities of life will not suit all places; for long experience has shown that all places are not equally healthy, or that the proportion of the number of persons that die annually, is different for different places. Dr. Halley computed a table of the annual deaths as drawn from the bills of mortality of the city of Breslaw in Germany: Mr. Smart and Mr. Simpson from those of London; Dr. Price from those of Northampton; Mr. Kersseboom from those of the provinces of Holland and West-Friesland; and M. Parcieux from the lists of the French tontines, or long annuities; and all these are found to differ from one another. It may not therefore be improper to insert here a comparative view of the principal tables that have been given of this kind, as below; where the first column shows the age, and the other columns the number of persons living at that age, out of 1000 born, or of the age 0, in the first line of each column.

TABLE I.—Showing the Number of Persons living at all Ages, out of 1000 that had been born at several Places, viz.

Ages.	Vienna.	Berlin.	London.	Norwich	Northampton.	Breslaw.	Brandenburg.	Holy-Cross.	Holland.	France.	Vaud, Switzerland.
0	1000	1000	1000	1000	1000	1000	1000	1000	1000	1000	1000

These tables show that the mortality and chance of life are various in different places; and that therefore, to obtain a sufficient accuracy in this business, it is necessary to adapt a table of probabilities or chances of life, to every place for which annuities are to be calculated; or at least one set of tables for large towns, and another for country places, as well as for the supposition of different rates of interest.

Several of the foregoing tables, as they commenced with different numbers, are here reduced to the same number at the beginning, viz, 1000 persons, by which means we are enabled by inspection, at any age, to compare the numbers together, and immediately perceive the relative degrees of vitality at the several places. The tables are also arranged according to the degree of vitality among them; the least, or that at Vienna, first; and the rest in their order, to the highest, which is the province of Vaud in Switzerland. The authorities on which these tables depend, are as they here follow. The first, taken from Dr. Price's Observations on Reversionary payments, is formed from the bills at Vienna, for 8 years, as given by Mr. Susmilch, in his *Gottliche Ordnung*; the 2d, for Berlin, from the same, as formed from the bills there for 4 years, viz, from 1752 to 1755; the 3d, from Dr. Price, showing the true probabilities of life in London, formed from the bills for ten years, viz, from 1759 to 1768; the 4th, for Norwich, formed by Dr. Price from the bills for

30 years, viz, from 1740 to 1769; the 5th, by the same, from the bills for Northampton; the 6th, as deduced by Dr. Halley, from the bills of mortality at Breslaw; the 7th shows the probabilities of life in a country parish in Brandenburg, formed from the bills for 50 years, viz, from 1710 to 1759, as given by Mr. Susmilch; the 8th shows the probabilities of life in the parish of Holy-Cross, near Shrewsbury, formed from a register kept by the Rev. Mr. Garsuch, for 20 years, from 1750 to 1770; the 9th, for Holland, was formed by M. Kersseboom, from the registers of certain annuities for lives granted by the government of Holland, which had been kept there for 125 years, in which the ages of the several annuitants dying during that period had been truly entered; the 10th, for France, were formed by M. Parcieux, from the lists of the French tontines, or long annuities, and verified by a comparison with the mortuary registers of several religious houses for both sexes; and the 11th, or last, for the district of Vaud in Switzerland, was formed by Dr. Price from the registers of 43 parishes given by M. Muret, in the Bern Memoirs for the year 1766.

Now from such lists as the foregoing, various tables have been formed for the valuation of annuities on single and joint lives, at several rates of interest, in which the value is shown by inspection.—The following are those that are given by Mr. Simpson, in his *Select Exercises*, as deduced from the London bills of mortality.

TABLE II.—Showing the Value of an Annuity on One Life, or Number of Years Annuity in the Value, supposing Money to bear Interest at the several Rates of 3, 4, and 5 per cent.

Age.	Years value at 3 per cent.	Years value at 4 per cent.	Years value at 5 per cent.	Age.	Years value at 3 per cent.	Years value at 4 per cent.	Years value at 5 per cent.

The uses of these tables may be exemplified in the following problems.

PROB. 1. To find the Probability or Proportion of Chance, that a Person of a Given Age continues in being a proposed number of years.—Thus, suppose the age be 40, and the number of years proposed 15; then, to calculate by the table of the probabilities for London, in tab. 1, against 40 years stands 214, and against 55 years, the age to which the person must arrive, stands 120, which shows that, of 214 persons who attain to the age of 40, only 120 of them reach the age of 55, and consequently 94 die between the ages of 40 and 55: It is evident therefore that the odds for attaining the proposed age of 55, are as 120 to 94, or as 9 to 7 nearly.

PROB. 2. To find the Value of an Annuity for a proposed Life.—This problem is resolved from tab. 2, by looking against the given age, and under the proposed rate of interest; then the corresponding quantity shows the number of years purchase required. For example, if the given age be 36, the rate of interest 4 per cent, and the proposed annuity 250: then in the table it appears that the value is 12·1 years purchase, or 12·1 times 250*t*, that is 3025*t*.

After the same manner the answer will be found in any other case falling within the limits of the table. But as there may sometimes be occasion to know the values of lives computed at higher rates of interest than those in the table, the two following practical rules are subjoined; by which the problem is resolved independently of tables.

Rule 1. When the given age is not less than 45 years nor greater than 85, subtract it from 92; then multiply the remainder by the perpetuity, and divide the product by the said remainder added to $2\frac{1}{2}$ times the perpetuity; so shall the quotient be the number of years purchase required. Where it is to be noted, that by the perpetuity is meant the number of years purchase of the fee-simple; found by dividing 100 by the rate per cent at which interest is reckoned.

Ex. Let the given age be 50 years, and the rate of interest 10 per cent. Then subtracting 50 from 92, there remains 42; which multiplied by 10 the perpetuity, gives 420; and this divided by 67, the remainder increased by $2\frac{1}{2}$ times the perpetuity, gives 6·3 nearly, for the number of years purchase. Therefore, supposing the annuity to be 100*t*, its value in present money will be 630*t*.

Rule 2. When the age is between 10 and 45 years; take 8 tenths of what it wants of 45, which divide by the rate per cent increased by 1·2; then if the quotient be added to the value of a life of 45 years, found by the preceding rule, there will be obtained the number of years purchase in this case. For example, let the proposed age be 20 years, and the rate of interest 5 per cent. Here then, taking 20 from 45, there remains 25; $\frac{8}{10}$ of which is 20; which divided by 6·2, gives 3·2; and this added to 9·8, the value of a life of 45, found by the former rule, gives 13 for the number of years purchase that a life of 20 ought to be valued at.

And the conclusions derived by these rules, Mr. Simp-

son adds, are so near the true values, computed from real observations, as seldom to differ from them by more than $\frac{1}{5}$ or $\frac{2}{5}$ of one year's purchase.

The observations here alluded to, are those which are founded on the London bills of mortality; and a similar method of solution, accommodated to the Breslaw observations, will be as follows, viz. "Multiply the difference between the given age and 85 years by the perpetuity, and divide the product by 8 tenths of the said difference increased by double the perpetuity, for the answer." Which, from 8 to 80 years of age, will commonly come within less than $\frac{1}{6}$ of a year's purchase of the truth.

P R O B . 3 . To find the Value of an Annuity for Two Joint Lives, that is, for as long as they both continue in being together.—In table 3, find the younger age, or that nearest to it, in column 1, and the higher age in column 2; then against this last is the number of years purchase in the proper column for the interest.—*Ex.* Suppose the two ages be 20 and 35 years; then the value

$$\begin{array}{ll} \text{is } 10\frac{9}{10} \text{ years purchase at 3 per cent.} \\ \text{or } 9\frac{8}{10} & - \quad \text{at 4 per cent.} \\ \text{or } 8\frac{8}{10} & - \quad \text{at 5 per cent.} \end{array}$$

P R O B . 4 . To find the Value of the Annuity for the Longest of Two Lives, that is, for as long as either of them continues in being.—In table 4, col. 1, find the age of the youngest life, or the nearest to it, in col. 1, and the age of the elder in col. 2: then against this last is the answer in the proper column of interest.—*Ex.* So, if the two ages be 15 and 40; then the value of the annuity upon the longest of two such lives

$$\begin{array}{ll} \text{is } 21\frac{1}{2} \text{ years purchase at 3 per cent.} \\ \text{or } 17\frac{9}{10} & - \quad 4 \text{ per cent.} \\ \text{or } 15\frac{7}{10} & - \quad 5 \text{ per cent.} \end{array}$$

In the last two problems, if the younger age, or the rate of interest, be not exactly found in the tables, the nearest to them may be taken, and then by proportion the value for the true numbers will be nearly found.

Rules and tables for the values of three lives, &c, may also be seen in Simpson, in Baron Maseres, and in Bailey's Annuities, &c. All these calculations have been made from tables of the real mortuary registers, differing unequally at the several ages: but rules have also been given on other principles, as by DeMoivre, on the supposition that the decrements of life are equal at all ages; an assumption not much differing from the truth, from 7 to 70 years of age.

L I F E - A N N U I T I E S , p a y a b l e h a l f - y e a r l y , &c.—These are worth more than those that are payable yearly, as computed by the foregoing rules and tables, on the two following accounts: First, that parts of the payments are received sooner; and 2dly, there is a chance of receiving some part or parts of a whole year's payment more than when the payments are only made annually. Mr. Simpson, in his Select Exercises, pa. 283, observes, that the value of these two advantages put together, will always amount to $\frac{1}{4}$ of a year's purchase for half-yearly payments, and to $\frac{3}{8}$ of a year's purchase for quarterly payments; and Mr. Maseres, at page 233 &c of his Annuities, by a very elaborate calculation, finds the former difference to be nearly $\frac{1}{4}$ also. But Dr. Price, in an essay in the Philos. Trans. vol. 66, pa. 109, states the same differences only

$$\begin{array}{l} \text{at } \frac{2}{5} \text{ for half-yearly payments,} \\ \text{and } \frac{3}{5} \text{ for quarterly payments:} \end{array}$$

And the doctor then adds some algebraical theorems for such calculations.

L I F E - A N N U I T I E S , s e c u r e d b y L a n d .—These differ from other life-annuities only in this, that the annuity is to be paid up to the very day of the death of the age in question, or of the person on whose life the annuity is granted. To obtain the more exact value therefore of such an annuity, a small quantity must be added to the same as computed by the foregoing rules and observations, which is different according as the payments are yearly, half-yearly, or quarterly, &c; and are thus stated by Dr. Price in his essay quoted above; viz, the addition

$$\text{is } \frac{y}{2n} \text{ for annual payments,}$$

$$\text{or } \frac{h}{4n} \text{ for half-yearly payments,}$$

$$\text{or } \frac{q}{8n} \text{ for quarterly payments :}$$

where n is the complement of the given age, or what it wants of 86 years; and y , h , q are the respective values of an annuity certain for n years, payable yearly, half-yearly, or quarterly. And, by numeral examples, it is found that the first of these additional quantities is about $\frac{2}{5}$, the second $\frac{1}{5}$, and the 3d half a tenth of one year's purchase.

L I G H T, that principle by which objects are made perceptible to our sense of seeing; or the sensation occasioned in the mind by the view of luminous objects. The nature of light has been a subject of speculation from the first dawning of philosophy. Some of the earliest philosophers doubted whether objects became visible by means of any thing proceeding from them, or from the eye of the spectator. But this opinion was qualified by Empedocles and Plato, who maintained, that vision was occasioned by particles continually flying off from the surfaces of bodies, which meet with others proceeding from the eye; while the effect was ascribed by Pythagoras solely to the particles proceeding from the external objects, and entering the pupil of the eye. But Aristotle defines light to be the act of a transparent body, considered as such: and he observes that light is not fire, nor any matter radiating from the luminous body, and transmitted through the transparent one.

The Cartesians have refined considerably on this notion: they maintain that light, as it exists in the luminous body, is only a power or faculty of exciting in us a very clear and vivid sensation; or that it is an invisible fluid present at all times and in all places, but requiring to be set in motion, by a body ignited or otherwise properly qualified to make objects visible to us.

Father Malbranche explains the nature of light from a supposed analogy between it and sound.—Thus, he supposes, all the parts of a luminous body are in a rapid motion, which, by very quick pulses, are constantly compressing the subtle matter between the luminous body and the eye, and excites vibrations of pression: and as these vibrations are greater, the body appears more luminous; but as they are quicker or slower, the body is of this or that colour.

The Newtonians maintain, that light is not a fluid per se, but consists of a great number of very small particles, thrown off from the luminous body by a repulsive power with an immense velocity, and in all directions: and these particles, they also assert, are emitted in right lines:

which rectilinear motion they preserve fill they are turned out of their path by some of the following causes, *yiz*, by the attraction of some other body near which they pass, which is called Inflection; or by passing obliquely through a medium of different density, which is called Refraction; or by being turned aside by the opposition of some intervening body, which is called Reflection; or, lastly, by being totally stopped by some substance into which they penetrate, and which is called their Extinction. A succession of these particles following one another, in an exact straight line, is called a Ray of Light; and this ray, in whatever manner its direction may be changed, whether by refraction, reflection, or inflection, always preserves a rectilinear course till it be again changed; neither, say they, is it possible to make it move in the arch of a circle, ellipsis, or other curve. For the above properties of the rays of light, see the several words, REFRACTION, REFLECTION, &c.

The velocity of the particles and rays of light is truly astonishing, amounting to near 2 hundred thousand miles in a second of time, which is near a million times greater than the velocity of a cannon-ball: and this amazing motion of light has been manifested in various ways, but chiefly from the eclipses of Jupiter's satellites. It was first observed by Roemer, that the eclipses of those satellites happen sometimes sooner, and sometimes later, than the times given by the tables of them; and that the observed time was before or after the computed time, according as the earth was nearer to, or farther from Jupiter. Hence Roemer and Cassini both concluded that this circumstance depended on the distance of Jupiter from the earth; and that, to account for it, they must suppose that the light was about 14 minutes in crossing the earth's orbit. This conclusion however was afterward abandoned and attacked by Cassini himself. But Roemer's opinion found an able advocate in Dr. Halley; who removed Cassini's difficulty, and left Roemer's conclusion in its full force. Yet, in a memoir presented to the academy in 1707, M. Maraldi endeavoured to strengthen Cassini's arguments; when Roemer's doctrine found a new defender in Mr. Pound. See Philos. Trans. number 136, also my Abridg. vol. 6, pa. 349 and 386, and Groves, Phys. Elem. number 2636: and it has since been found, by repeated experiments, that when the earth is exactly between Jupiter and the sun, his satellites are seen eclipsed about $8\frac{1}{2}$ minutes sooner than they could be according to the tables; but when the earth is nearly in the opposite point of its orbit, these eclipses happen about $8\frac{1}{2}$ minutes later than the tables predict them. Hence then it is certain that the motion of light is not instantaneous, but that it takes up about $16\frac{1}{2}$ minutes of time to pass over a space equal to the diameter of the earth's orbit, which is at least 190 millions of miles in length, or at the rate of near 200,000 miles per second, as above stated. Hence it is easy to know the time in which light travels to the earth, from the moon, or any of the other planets, or even from the fixed stars if ever their distances be known; but these distances are so immensely great, that from the nearest of them, supposed to be Sirius, the dog-star, it requires many years for light to travel to the earth: and it has even been conjectured that there are many stars whose light have not yet arrived at us since their creation.

It was Galileo who first conceived the notion of measuring the velocity of light; and a description of his contrivance for this purpose, is given in his Treatise on Me-

chanics, pa. 39. He had two men with lights covered; the one was to observe when the other uncovered his light, and to exhibit his own the moment he perceived it. This rude experiment was tried at the distance of a mile, but without success, as may naturally be imagined: and the members of the academy Del Cimento repeated the experiment, and placed their observers, to as little purpose, at the distance of 2 miles.

But our excellent astronomer, Dr. Bradley, afterwards found nearly the same velocity of light as Roemer, from his accurate observations, and most ingenious theory, to account for some apparent motions in the fixed stars; for an account of which, see ABERRATION of light. By a long series of these observations, he found the difference between the true and apparent place of several fixed stars, for different times of the year; which difference could no otherwise be accounted for, than from the progressive motion of the rays of light. From the mean quantity of this difference he found, that the ratio of the velocity of light to the velocity of the earth in its orbit, was as 10313 to 1, or that light moves 10313 times faster than the earth moves in its orbit about the sun; and as this latter motion is at the rate of $18\frac{1}{2}$ miles per second nearly, it follows that the former, or the velocity of light, is at the rate of about 195000 miles in a second; a motion according to which it will require just 8⁷/₁₀ to move from the sun to the earth, or about 95 millions of miles.

It was also inferred, from the foregoing principles, that light proceeds with the same velocity from all the stars. And hence it follows, that the motion of light, in its path through the immense space above our atmosphere, is equable or uniform. And since the different methods of determining the velocity of light thus agree in the result, it is reasonable to conclude that, in the same medium, light is propagated, after it has been reflected, with the same velocity as before. For an account of Mr. Melville's hypothesis of the different velocities of differently coloured rays, see COLOUR.

To the doctrine concerning the materiality of light, and its amazing velocity, several objections have been made; of which the most considerable is, That as rays of light are continually passing in different directions from every visible point, they must necessarily interfere with each other in such a manner, as entirely to confound all distinct perception of objects, if not quite to destroy the whole sense of seeing: not to mention the continual waste of substance which a constant emission of particles must occasion in the luminous body, and thereby since the creation must have greatly diminished the matter in the sun and stars, as well as increased the bulk of the earth and planets by the vast quantity of particles of light absorbed by them in so long a period of time.

But it has been replied, that if light were not a body, but consisted in mere pressure or pulsion, it could never be propagated in right lines, but would be continually inflected ad umbram. Thus Sir I. Newton: "A pressure on a fluid medium, i. e. a motion propagated by such a medium, beyond an obstacle, which impedes any part of its motion, cannot be propagated in right lines, but will be always inflecting and diffusing itself every way, to the quiescent medium beyond that obstacle. The power of gravity tends downwards; but the pressure of water arising from it tends every way with an equable force, and is propagated with equal ease and equal strength, in curves, as in straight lines. Waves, on the surface of the water, gliding

by the extremes of any very large obstacle, inflect and dilate themselves, still diffusing gradually into the quiescent water beyond that obstacle. The waves, pulses, or vibrations of the air, wherein sound consists, are manifestly inflected, though not so considerably as the waves of water; and sounds are propagated with equal ease, through crooked tubes, and through straight lines; but light was never known to move in any curve, nor to inflect itself ad umbram."

It must be acknowledged however, that many philosophers, both English and foreigners, have recurred to the opinion, that light consists of vibrations propagated from the luminous body, through a subtle etherial medium. The ingenious Dr. Franklin, in a letter dated April 23, 1752, expresses his dissatisfaction with the doctrine of light consisting of particles of matter continually driven off from the sun's surface, with such an astonishing velocity. "Must not," says he, "the smallest portion conceivable, have, with such a motion, a force exceeding that of a 24 pounder discharged from a cannon? Must not the sun diminish exceedingly by such a waste of matter; and the planets, instead of drawing nearer to him, as some have feared, recede to greater distances through the diminished attraction? Yet these particles, with this amazing motion, will not drive before them, or remove, the least and slightest dust they meet with; and the sun appears to continue of his ancient dimensions, and his attendants move in their ancient orbits." He therefore conjectures that all the phenomena of light may be more properly solved, by supposing all space filled with a subtle elastic fluid, which is not visible when at rest, but which, by its vibrations, affects that fine sense in the eye, as those of the air affect the grosser organs of the ear; and even that different degrees of the vibration of this medium may cause the appearances of different colours. Franklin's Exper. and Observ. 1769, pa. 264.

The celebrated Euler has also maintained the same hypothesis, in his *Theoria Lucis et Colorum*. In the summary of his arguments against the common opinion, recited in Acad. Berl. 1752, pa. 271, besides the objections above mentioned, he doubts the possibility, of particles of matter, moving with the amazing velocity of light, and penetrating transparent substances with so much ease. In whatever manner they are transmitted, those bodies must have pores, disposed in right lines, and in all possible directions, to serve as canals for the passage of the rays: but such a structure must take away all solid matter from those bodies, and all coherence among their parts, if they do contain any solid matter.

Doctor Horsley has taken considerable pains to obviate the difficulties started by Dr. Franklin. Supposing that the diameter of each particle of light does not exceed one millionth of one millionth of an inch, and that the density of each particle is even 3 times that of iron, and also that the light of the sun reaches the earth in 7', at the distance of 22919 of the earth's semidiameters, he calculates that the momentum or force of motion in each particle of light coming from the sun, is less than that in an iron ball of a quarter of an inch diameter, moving at the rate of less than an inch in 12 thousand millions of millions of years. And hence he concludes, that a particle of matter, which probably is larger than any particle of light, moving with the velocity of light, has a force of motion, which, instead of exceeding the force of a 24-pounder discharged from a cannon, is almost infinitely

less than that of the smallest shot discharged from a pocket-pistol, or less than any that art can create. He also thinks it possible, that light may be produced by a continual emission of matter from the sun, without any such waste of his substance as should sensibly contract his dimensions, or alter the motions of the planets, within any moderate length of time. In proof of this, he observes that, for the production of any of the phenomena of light, it is not necessary that the emanation from the sun should be continual, in a strict mathematical sense, or without any interval; and likewise that part of the light which issues from the sun, is continually returned to him by reflection from the planets, as well as other light from the suns of other systems. He proceeds, by calculation, to show, that in 385,130,000 years, the sun would lose but the 1323rd part of his matter, and consequently of the gravitation towards him, at any given distance; which is an alteration much too small to discover itself in the motion of the earth, or of any of the planets. He further computes that the greatest stroke which the retina of a common eye sustains, when turned directly to the sun in a bright day, does not exceed that which would be given by an iron shot, a quarter of an inch diameter, and moving only at the rate of 16 $\frac{1}{2}$ inches in a year; whereas the ordinary stroke is less than the 2084th part of this. See Philos. Trans. vol. 60 and 61.

In answer to the difficulty respecting the interference of the particles of light with each other, Mr. Melville observes (Edinab. Ess. vol. 2), there is probably no physical point in the visible horizon, that does not send rays to every other point, unless where opaque bodies interpose. Light, in its passage from one system to another, often passes through torrents of light issuing from other suns and systems, without ever interfering, or being diverted from its course, either by it, or by the particles of that elastic medium, which has been supposed by some diffused through all the mundane space. To account for this fact, he supposes that the particles of light are incomparably rare, even when they are the most dense, or that their diameters are incomparably less than their distance from one another: which obviates the objection urged by Euler and others against the materiality of light, from its influence in disturbing the freedom and perpetuity of the celestial motions. Boscovich and some others solve the difficulty concerning the non-interference of the particles of light, by supposing that each particle is endowed with an insuperable impulsive force; but in this case, their spheres of impulsion would be more likely to interfere, and on that account they would be more liable to disturb one another.

Mr. Canton shows (Philos. Trans. vol. 58, pa. 344), that the difficulty of the interference will vanish, if a very small portion of time be allowed between the emission of every particle and the next that follows in the same direction. Suppose, for instance, that a lucid point in the sun's surface emits 150 particles in a second of time, which, he observes, will be more than sufficient to give continual light to the eye, without the least appearance of intermission; yet still the particles of such a ray, on account of their great velocity, will be more than 1000 miles behind each other, a space sufficient to allow others to pass in all directions without any perceptible interruption. And if we adopt the conclusions drawn from the experiments on the duration of the sensations excited by light, by the chevalier D'Arcy, in the Acad. Scien. 1765, who

states it at the 7th part of a second, an interval of more than 20,000 miles may be admitted between every two successive particles.

The doctrine of the materiality of light is further confirmed by those experiments, which show, that the colour and inward texture of some bodies are changed by being exposed to the light.

Of the Momentum, or Force, of the Particles of Light. Some writers have attempted to prove the materiality of light, by determining the momentum of their component particles, or by showing that they have a force, so as, by their impulse, to give motion to light bodies. M. Homberg, Ac. Par. 1708, Hist. pa. 25, imagined, that he could not only disperse pieces of amianthus, and other light substances, by the impulse of the solar rays, but also that by throwing them upon the end of a kind of lever, connected with the spring of a watch, he could make it move sensibly quicker; from which, and from other experiments, he inferred the weight of the particles of light. And Hartsoeker made pretensions of the same nature. But M. Du Fay and M. Mairan made other experiments of a more accurate kind, without the effects which the former had imagined, and which even proved that the effects mentioned by them were owing to currents of heated air produced by the burning glasses used in their experiments, or some other causes which they had overlooked.

Dr. Priestley, however, informs us, that Mr. Michell endeavoured to ascertain the momentum of light with still greater accuracy, and that his endeavours were not altogether without success. Having found that the instrument he used, acquired, from the impulse of the rays of light, a velocity of an inch in a second of time, he inferred that the quantity of matter contained in the rays falling upon the instrument in that time, amounted to no more than the 12 hundred millionth part of a grain. In the experiment, the light was collected from a surface of about 3 square feet; and as this surface reflected only about the half of what fell upon it, the quantity of matter contained in the solar rays, incident upon a square foot and a half of surface, in a second of time, ought to be no more than the 12 hundred millionth part of a grain, or upon one square foot only, the 18 hundred millionth part of a grain. But as the density of the rays of light at the surface of the sun, is 45000 times greater than at the earth, there ought to issue from a square foot of the sun's surface, in one second of time, the 40 thousandth part of a grain of matter; that is, a little more than 2 grains a day, or about 4,752,000 grains, which is about 670 pounds avoirdupois, in 6000 years, the time since the creation; a quantity which would have shortened the sun's semidiameter by no more than about 10 feet, if it be supposed of no greater density than water only.

The Expansion or Extension of any portion of light, is inconceivable. Dr. Hooke shows that it is as unlimited as the universe; this he proves from the immense distance of many of the fixed stars, which only become visible to the eye by the best telescopes. Nor, adds he, are they only the great bodies of the sun or stars that are thus liable to disperse their light through the vast expanse of the universe, but the smallest spark of a lucid body must do the same, even the smallest globule struck from a steel by a flint.

The Intensity of different lights, or of the same light in different circumstances, affords a curious subject of speculation. M. Bouguer, in his *Traité de Optique*, found that when one

light is from 60 to 80 times less than another, its presence or absence will not be perceived by an ordinary eye; that the moon's light, when she is $19^{\circ} 16'$ high above the horizon, is but about $\frac{1}{3}$ of her light at $66^{\circ} 11'$ high; and when one limb just touched the horizon, her light is but the 2000th part of her light at $66^{\circ} 11'$ high; and that hence light is diminished in the proportion of 3 to 1 by traversing 7469 toises of dense air. He found also, that the centre of the sun's disc is considerably more luminous than the edges of it; whereas both the primary and secondary planets are more luminous at their edges than near their centres: That, further, the light of the sun is about 300,000 times greater than that of the moon; and therefore it is no wonder that philosophers have had so little success in their attempts to collect the light of the moon with burning-glasses; for, should one of the largest of them even increase the light 1000 times, it will still leave the light of the moon in the focus of the glass, 300 times less than the intensity of the common light of the sun.

Dr. Smith, in his *Optics*, vol. 1, pa. 29, thought he had proved that the light of the full moon would be only the 90,900th part of the full day light, if no rays were lost at the moon. But Mr. Robins, in his *Tracts*, vol. 2, pa. 225, shows that this is too great by one half. And Mr. Michell, by a more easy and accurate mode of computation, found that the density of the sun's light on the surface of the moon is but the 45,000th part of the density at the sun; and that therefore, as the moon is nearly of the same apparent magnitude as the sun, if she reflected to us all the light received on her surface, it would be only the 45,000th part of our day light, or that which we receive from the sun. Admitting therefore, with M. Bouguer, that the moon's light is only the 300,000th part of the day or sun's light, Mr. Michell concludes that the moon reflects no more than between the 6th and 7th part of what she receives.

Dr. Gravescande says, a lucid body is that which emits or gives fire a motion in right lines, and makes the difference between light and heat to consist in this, that to produce the former, the fiery particles must enter the eye in a rectilinear motion, which is not required in the latter: on the contrary, an irregular motion seems more proper for it, as appears from the rays coming directly from the sun to the tops of mountains, which have not near that effect with those in the valley, agitated with an irregular motion, by several reflections.

Sir I. Newton observes, that bodies and light act mutually on each other; bodies on light, in emitting, reflecting, refracting, and inflecting it; and light on bodies, by heating them, and putting their parts into a vibrating motion, in which heat principally consists. For all fixed bodies, he observes, when heated beyond a certain degree, do emit light, and shine; which shining &c appears to be owing to the vibrating motion of their parts; and all bodies, abounding in earthy and sulphureous particles, if sufficiently agitated, emit light, which way sooner that agitation be effected. Thus, sea water shines in a storm; quicksilver, when shaken in vacuo; cats or horses, when rubbed in the dark; and wood, fish, and flesh, when putrefied.

Light proceeding from putrescent animal and vegetable substances, as well as from glow-worms, is mentioned by Aristotle. And Bartholin mentions four kinds of luminous insects, two of which have wings: but in hot climates it is said they are found in much greater numbers, and of

different species. Columna observes, that their light is not extinguished immediately on the death of the animal. The first distinct account that occurs of light proceeding from putrescent animal flesh, is that which is given by Fabricius ab Aquapendente in 1592, de Visione &c, pa. 45. And Bartholin relates also a similar appearance in his treatise De Luce Animalium, which happened at Montpelier in 1641.

Mr. Boyle speaks of a piece of shining rotten wood which was extinguished *in vacuo*; but on re-admitting the air, it revived again, and shone as before; though he could not perceive that it was increased in condensed air. But in Birch's History of the Royal Society, vol. 2, pa. 254, there is an account of the light of a shining fish, which was rendered more vivid by putting the fish into a condensing engine. Whiting were the fish commonly used by Mr. Boyle in his experiments: though in a discourse read before the Royal Society in 1681, it was asserted that, of all fishy substances, the eggs of lobsters, after they had been boiled, shone the brightest. Birch's Hist. vol. 2, pa. 70. In 1672 Mr. Boyle accidentally observed light issuing from flesh meat; and, among other remarks on this subject, he observes that extreme cold extinguishes the light of shining wood; probably because extreme cold checks the putrefaction, which is the cause of the light. The shell fish called pholas, is remarkable for its luminous quality. The luminousness of the sea has been also a subject of frequent observation. See *IGNIS FATUUS*, *PHILOSOPHUS*, and *PUTREFACTION*, &c.

Mr. Hawksbee, and many writers on the subject of electricity since his time, have produced a great variety of instances of the artificial production of light, by the attrition of bodies naturally not luminous; as of amber rubbed on woollen cloth *in vacuo*; of glass on woollen, of glass on glass, of oyster shells on woollen, and of woollen on woollen, all *in vacuo*. On the several experiments of this kind, he makes the following reflections: that different sorts of bodies afford light of various kinds, with regard both to colour and force; that the effects of an attrition are various, according to the different preparations and treatment of the bodies which are to endure it; and that bodies which have yielded a particular light, may be brought by friction to yield no more of that light.

M. Bernoulli found by experiment, that mercury amalgamated with tin, and rubbed on glass, produced a considerable light in the air; that gold rubbed on glass, exhibited the same in a greater degree; but that the most exquisite light of all was produced by the attrition of a diamond, this being equally vivid with that of a burning coal briskly agitated with the bellows. See *ELECTRICITY*, &c.

Of the Attraction of Light. That the particles of light are attracted by those of other bodies, is evident from numerous experiments. This phenomenon was observed by Sir I. Newton, who found, by repeated trials, that the rays of light, in their passage near the edges of bodies, are diverted out of the right lines, and always inflected or bent towards those bodies, whether they be opaque or transparent, as pieces of metals, the edges of knives, broken glasses, &c. See *INFLECTION* and *RAYS*. The curious observations that had been made on this subject by Dr. Hooke and Grimaldi, led Sir I. Newton to repeat and diversify their experiments, and to pursue them much farther than they had done. For a particular account of his experiment and observations, see his treatise on Optics, pa. 293, &c.

This action of bodies on light is found to exert itself at a sensible distance, though it always increases as the distance is diminished; as appears very sensibly in the passage of a ray between the edges of two thin planes at different apertures; which is attended with this peculiar circumstance, that the attraction of one edge is increased as the other is brought nearer to it. The rays of light, in their passage out of glass into a vacuum, are not only inflected towards the glass, but if they fall too obliquely, they will revert back again to the glass, and be totally reflected. Now the cause of this reflection cannot be attributed to any resistance of the vacuum, but must be entirely owing to some force or power in the glass, which attracts or draws back the rays as they were passing into the vacuum. And this appears to be further confirmed from hence, that if you wet the back surface of the glass with water, oil, honey, or a solution of quicksilver, then the rays which would otherwise have been reflected, will pervade and pass through that liquor; which shows that the rays are not reflected till they come to that back surface of the glass, nor even till they begin to go out of it; for if, at their going out, they fall into any of the aforesaid mediums, they will not then be reflected, but will persist in their former course, the attraction of the glass being in this case counterbalanced by that of the liquor.

M. Maraldi prosecuted experiments similar to those of Sir I. Newton on inflected light. And his observations chiefly respect the inflection of light towards other bodies, by which their shadows are partially illuminated. Acad. Paris 1723, Mem. pa. 159. See also Priestley's Hist. pa. 521, &c.

M. Mairan, without attempting the discovery of new facts, endeavoured to explain the old ones, by the hypothesis of an atmosphere surrounding all bodies; and consequently two reflections and refractions of light that impinge on them, one at the surface of the atmosphere, and the other at the surface of the body itself. This atmosphere he supposed to be of a variable density and refractive power, like the air.

M. Dutour succeeded Mairan, and imagined that he could account for all the phenomena by the help of an atmosphere of a uniform density, but of a less refractive power than the air surrounding all bodies. Dutour also varied the Newtonian experiments, and discovered more than three fringes in the colours produced by the inflection of light. He further concludes that the refracting atmospheres, surrounding all kinds of bodies, are of the same size; for when he used a great variety of substances, and of different dimensions, he always found coloured streaks of the same dimensions. He also observes, that this hypothesis contradicts an observation of Sir I. Newton, viz, that those rays are the most inflected which pass the nearest to any body. Mem. de Math. et de Phys. vol. 5, pa. 650, or Priestley's Hist. pa. 531.

M. Lecat found that objects sometimes appear magnified by means of the inflection of light. Looking at a distant steeple, when a wire, of a less diameter than the pupil of his eye, was held pretty near to it, and drawing it several times between that object and his eye, he was surprised to find that every time the wire passed before his eye, the steeple seemed to change its place, and some hills beyond the steeple seemed to have the same motion, just as if a lens had been drawn between them and his eye. This discovery led him to several others depending on the inflection of the rays of light. Thus, he magnified small

objects, as the head of a pin, by viewing them through a small hole in a card; so that the rays which formed the image must necessarily pass so near the circumference of the hole, as to be attracted by it. He exhibited also other appearances of a similar nature. *Traité des Sens*, pa. 299. Priestley, *ubi supra*, pa. 537.

Reflection and Refraction of Light. From the mutual attraction between the particles of light and other bodies, arise two other grand phenomena, besides the inflection of light, which are called the reflection and refraction of light. It is well known that the determination of bodies in motion, especially elastic ones, is changed by the interposition of other bodies in their way: thus also light, impinging on the surfaces of bodies, should also be turned out of its course, and beaten back or reflected, so as, like other striking bodies, to make the angle of its reflection equal to the angle of incidence. This, it is found by experience, light does; and yet the cause of this effect is different from that just now assigned: for the rays of light are not reflected by striking on the very parts of the reflecting bodies, but by some power equally diffused over the whole surface of the body, by which acts on the light, either attracting or repelling it, without contact: by which same power, in other circumstances, the rays are refracted; and by which also the rays are first emitted from the luminous body; as Newton fully proves by a great variety of arguments. See REFLECTION and REFRACTION.

That great author proves, that all those rays which are reflected, do not really touch the body, though they approach infinitely near to it; and that those which strike on the parts of solid bodies, adhere to them, and are as it were extinguished and lost. Since the reflection of the rays is ascribed to the action of the whole surface of the body without contact, if it be asked, how it happens that all the rays are not reflected from every surface; but that, while some are reflected, others pass through, and are refracted? the answer given by Newton is as follows:—Every ray of light, in its passage through any refracting surface, is put into a certain transient constitution or state, which in the progress of the ray returns at equal intervals, and disposes the ray at every return to be easily transmitted through the next refracting surface, and between the returns to be easily reflected by it: which alteration of reflection and transmission it appears is propagated from every surface, and to all distances. What kind of action or disposition this is, and whether it consists in a circulating or vibrating motion of the ray, or the medium, or something else, he does not enquire; but allows those who are fond of hypotheses to suppose, that the rays of light, by impinging on any reflecting or refracting surface, excite vibrations in the reflecting or refracting medium, and by that means agitate the solid parts of the body. These vibrations, thus produced in the medium, move faster than the rays, so as to overtake them; and when any ray is in that part of the vibration which conspires with its motion, its velocity is increased, and so it easily breaks through a refracting surface; but when it is in a contrary part of the vibration, which impedes its motion, it is easily reflected; and thus every ray is successively disposed to be easily reflected or transmitted by every vibration which meets it. These returns in the disposition of any ray to be reflected, he calls Fits of Easy Reflection; and the returns in the disposition to be transmitted, he calls Fits of Easy Transmission; also the space between the returns, the Interval of the Fits. Hence then the reason why the surfaces

of all thick transparent bodies reflect part of the light incident on them, and refract the rest, is, that some rays at their incidence are in fits of easy reflection, and others of easy transmission. For the properties of reflected Light, see REFLECTION, MIRROR, &c.

Again, a ray of light, passing out of one medium into another of different density, and in its passage making an oblique angle with the surface that separates the mediums, will be refracted, or turned out of its direction; because the rays are more strongly attracted by a denser than by a rarer medium. That these rays are not refracted by striking on the solid parts of bodies, but that this is effected without a real contact, and by the same force by which they are emitted and reflected, only exerting itself differently in different circumstances, is proved in a great measure by the same arguments by which it is demonstrated that reflection is performed without contact. See REFRACTION, LENS, COLOUR, VISION, &c.

Chemical Properties of Light.—The chemical properties of light are yet but very imperfectly known, though there is reason to believe that it is an agent of great importance in many of the principal changes that are going on in the visible world, and even in the experiments of the laboratory its effects are often clearly demonstrable.

The process of rapid combustion is always attended with the evolution of light along with heat, the source of both of which is ascribed by Lavoisier to the oxygen, which is known to be essential to combustion; so that according to this eminent philosopher, while any substance is burning, the oxygen alone unites with the combustible substance, forming an oxyd, acid, &c, according to circumstances; and both the light and heat which previously existed in the oxygen are now set at liberty, and appear in the form of visible flame.

But there are many weighty objections to the latter part of this hypothesis (see Oxygen and Combustion), so that many chemists have returned to the old opinion, that the light is derived from the burning body, and not from the oxygen that supports combustion; an opinion which on the whole better agrees with the observed phenomena.

The sun's rays, the great source of light and heat to our world, have been found by Dr. Herschel to contain, besides all the common coloured rays, separable by the prism, a number of rays of mere heat, giving no light, still less refrangible than the red rays of the spectrum, and therefore extending beyond them, and producing a greater heat than any of the visible rays. Since that time it has been discovered, as appears both by Dr. Wollaston, Philosophical Trans., for 1802, and Mr. Ritter, Philosophical Journal, 8vo, vols. 4 and 8, that beyond the opposite, or violet side of the prism, are certain other rays, also invisible, which do not effect the thermometer, but which produce some of the chemical effects of the visible rays of light, particularly of the violet rays to which they are contiguous. These therefore appear to be, if the expression may be allowed, *invisible rays of light*, or rays which, though they do not illuminate, agree in chemical properties with those that do, and appear to be more than any other, separate from solar heat.

The most rapid and most unexceptionable chemical effects of pure light hitherto discovered, has been the change of colours of white *luna cornea*, to a purplish brown, or slate colour. This change takes place without requiring the least increase of temperature, or in any way being affected by heat or cold, and it occurs equally well

in close as in open vessels, and only on the surface immediately exposed to the light. *Akin's Chem. Dict.*

LIGHTNING, a large bright flame, shooting swiftly through the atmosphere, of momentary or very short duration, and commonly attended with thunder.

Some philosophers accounted for this awful natural phenomenon in this manner, viz, that an inflammable substance is formed of the particles of sulphur, nitre, and other combustible matter, which are exhaled from the earth, and carried into the higher regions of the atmosphere, and that by the collision of two clouds, or otherwise, this substance takes fire, and darts out into a train of light, larger or smaller according to the strength and quantity of the materials. And others have explained the phenomenon of lightning by the fermentation of sulphureous substances with nitrous acids. See THUNDER.

But it is now universally allowed, that lightning is really an electrical explosion or phenomenon. Philosophers had not proceeded far in their experiments and enquiries on this subject, before they perceived the obvious analogy between lightning and electricity, and they produced many arguments to evince their similarity. But the method of proving this hypothesis beyond a doubt, was first proposed by Dr. Franklin, who, about the close of the year 1749, conceived the practicability of drawing lightning down from the clouds. Various circumstances of resemblance between lightning and electricity were remarked by this ingenious philosopher, and have been abundantly confirmed by later discoveries, such as the following: Flashes of lightning are usually seen crooked and waving in the air; so the electric spark drawn from an irregular body at some distance, and when it is drawn by an irregular body, or through a space in which the best conductors are disposed in an irregular manner, always exhibits the same appearance: lightning strikes the highest and most pointed objects in its course, in preference to others, as hills, trees, spires, masts of ships, &c; so all pointed conductors receive and throw off the electric fluid more readily than those that are terminated by flat surfaces: lightning is observed to take and follow the readiest and best conductor; and the same is the case with electricity in the discharge of the Leyden phial; whence the doctor infers, that in a thunder-storm, it would be safer to have one's clothes wet than dry; lightning burns, dissolves metals, rends some bodies, sometimes strikes persons blind, destroys animal life, deprives magnets of their virtue, or reverses their poles; and all these are well-known properties of electricity.

But lightning also gives polarity to the magnetic needle, as well as to all bodies that have any thing of iron in them, as bricks &c; and by observing afterwards which way the magnetic poles of these bodies lie, it may thence be known in what direction the stroke passed. Persons are sometimes killed by lightning, without exhibiting any visible marks of injury; and in this case Sig. Beccaria supposes that the lightning does not really touch them, but only produces a sudden vacuum near them, and the air rushing violently out of their lungs to supply it, they cannot recover their breath again: and in proof of this opinion he alleges, that the lungs of such persons are found flaccid; whereas these are found inflated when the persons are really killed by the electric shock. This hypothesis however is controverted by Dr. Priestley.

To demonstrate by actual experiment, the identity of the electric fluid with the matter of lightning, Dr. Frank-

lin contrived to bring lightning from the heavens, by means of a paper kite, properly fitted up for the purpose, with a long fine wire string, and called an electrical kite, which he raised when a thunder-storm was perceived to be coming on: and with the electricity thus obtained, he charged phials, kindled spirits, and performed all other such electrical experiments as are usually exhibited by an excited glass globe or cylinder. This happened in June 1752, a month after the electricians in France, in pursuance of the method which he had before proposed, had verified the same theory. The most active of these were Messrs. Dalibard and Delor, followed by M. Mazeas and M. Monnier.

In April and June 1753, Dr. Franklin discovered that the air is sometimes electrified negatively, as well as sometimes positively; and he even found that the clouds would change from positive to negative electricity several times in the course of one thunder-gust. This curious and important discovery he soon perceived was capable of being applied to practical use in life, and in consequence proposed a method, which he soon accomplished, of securing buildings from being damaged by lightning, by means of CONDUCTORS: which see.

Nor had the English philosophers been inattentive to this subject: but, for want of proper opportunities of trying the necessary experiments, and from some other unfavourable circumstances, they had failed of success. Mr. Canton, however, succeeded in July 1752; and in the following month Dr. Bevis and Mr. Wilson observed nearly the same appearances as Mr. Canton had done before. By a number of experiments Mr. Canton also soon after observed that some clouds were in a positive, while some were in a negative state of electricity; and that the electricity of his conductor would sometimes change, from one state to the other, five or six times in less than half an hour.

But Sig. Beccaria discovered this variable state of thunder clouds, before he knew that it had been observed by Dr. Franklin or any other person; and he has given a very exact and particular account of the external appearances of these clouds. From the observations of his apparatus within doors, and of the lightning abroad, he inferred, that the quantity of electric matter in a common thunder-storm, is inconceivably great, considering how many pointed bodies, as spires, trees, &c, are continually drawing it off, and what a prodigious quantity is repeatedly discharged to or from the earth. This matter is in such abundance, that he thinks it impossible for any cloud or number of clouds to contain it all, so as either to receive or discharge it. He observes also, that during the progress and increase of the storm, though the lightning frequently struck to the earth, the same clouds were the next moment ready to make a still greater discharge, and his apparatus continued to be as much affected as ever; so that the clouds must have received at one part, in the same moment when a discharge was made from them in another. And from the whole he concludes, that the clouds serve as conductors to convey the electric fluid from those parts of the earth that are overloaded with it, to those that are exhausted of it. The same cause by which a cloud is first raised, from vapours dispersed in the atmosphere, draws to it those that are already formed, and still continues to form new ones, till the whole collected mass extends so far as to reach a part of the earth where there is a deficiency of the electric fluid, and where the electric matter will discharge itself on the earth. A chan-

nel of communication being thus formed, a fresh supply of electric matter is raised from the overloaded part, which continues to be conveyed by the medium of the clouds, till the equilibrium of the fluid is restored between the two places of the earth. Sig. Beccaria observes, that a wind always blows from the place from which the thunder-cloud proceeds; and it is plain that the sudden accumulation of such a prodigious quantity of vapours must displace the air, and repel it on all sides. Indeed many observations of the descent of lightning confirm his theory of the manner of its ascent; for it often throws before it the parts of conducting bodies, and distributes them along the resisting medium, through which it must force its passage; and on this principle, the longest flashes of lightning seem to be made, by forcing into its way part of the vapours in the air. One of the chief reasons why these flashes make so long a rumbling, is that they are occasioned by the vast length of a vacuum made by the passage of the electric matter: for though the air collapses the moment after it has passed, and that the vibration, on which the sound depends, commences at the same moment; yet when the flash is directed towards the person who hears the report, the vibrations excited at the nearer end of the track, will reach his ear much sooner than those from the more remote end; and the sound will, without any echo or repercussion, continue till all the vibrations have successively reached him.

How it happens that particular parts of the earth, or the clouds, come into the opposite states of positive and negative electricity, is a question not absolutely determined: though it is easy to conceive that when particular clouds, or different parts of the earth, possess opposite electricities, a discharge will take place within a certain distance; or the one will strike into the other, and in the discharge a flash of lightning will be seen. Mr. Canton queries whether the clouds do not become possessed of electricity by the gradual heating and cooling of the air; and whether air suddenly rarefied, may not give electric fire to clouds and vapours passing through it, and air suddenly condensed receive electric fire from them.—Mr. Wilcke supposes, that the air contracts its electricity in the same manner that sulphur and other substances do, when they are heated and cooled in contact with various bodies. Thus, the air being heated or cooled near the earth, gives electricity to the earth, or receives it from it; and the electrified air, being conveyed upwards by various means, communicates its electricity to the clouds.—Others have queried, whether, since thunder commonly happens in a sultry state of the air, when it seems charged with sulphureous vapours, the electric matter then in the clouds may not be generated by the fermentation of sulphureous vapours with mineral or acid vapours in the air.

With regard to places of safety in times of thunder and lightning, Dr. Franklin's advice is, to sit in a chair in the middle of a room, provided it be not under a metal lustre suspended by a chain, and laying the feet on another chair. "It is still better," he says, "to bring two or three mattresses or beds into the middle of the room, and folding them double, to place the chairs upon them; for as they are not so good conductors as the walls, the lightning will not be so likely to pass through them: but the safest place of any, is in a hammock hung by silken cords, at an equal distance from all the sides of a room. Dr. Priestley however observes, that the place of most perfect safety must be a cellar, and especially the middle of it; for when a

person is lower than the surface of the earth, the lightning must strike it before it can possibly reach him. In the fields, the most secure place is within a few yards of a tree, but not quite near it. Beccaria cautions persons not always to trust too much to the neighbourhood of a higher or better conductor than their own body; since he has repeatedly found that the lightning by no means descends in one undivided track, but that bodies of various kinds conduct their share of it at the same time, in proportion to their quantity and conducting power. See Franklin's Letters, Beccaria's *Lettre dell' Elettricissimo*; Priestley's Hist. of Electric., and Lord Mahon's Principles of Electricity.

Lord Mahon observes that damage may be done by lightning, not only by the main stroke and lateral explosion, but also by what he calls the returning stroke; by which is meant the sudden violent return of that part of the natural share of electricity which had been gradually expelled from some body or bodies, by the superinduced elastic electrical pressure of the electrical atmosphere of a thunder-cloud.

Artificial Lightning, an imitation of real or natural lightning by gunpowder, aurum fulminans, phosphorus, &c, but especially the last, between which and lightning there is much more resemblance than the others. Phosphorus, when newly made, gives a sort of artificial lightning visible in the dark, which would surprise those not used to such a phenomenon. It is usual to keep this preparation under water; and if it is desired to see the coruscations to the greatest advantage, it should be kept in a deep cylindrical glass, not more than three quarters filled with water. At times the phosphorus will send up coruscations, which will pierce through the incumbent water, and expand themselves with great brightness in the upper or empty part of the glass, and much resembling lightning. The phosphorus, while burning, acts the part of a corrosive, and when it goes out resolves into a menstruum, which dissolves gold, iron, and other metals; and lightning, in like manner, melts the same substances.

LIKE QUANTITIES, or Similar Quantities, in Algebra, are such as are expressed by the same powers of the same letters, or equally repeated in each quantity; though the numerical coefficients may be different.

Thus $4a$ and $5a$ are like quantities,

as are also $3a^2$ and $12a^2$,
and also $6bry^2$ and $10bry^2$.

But $4a$ and $5b$, or $3a^2b$ and $10a^2b^2$, &c, are unlike quantities; because they have not the same dimensions throughout, nor are the letters equally repeated.—Like quantities can be united into one quantity, by addition or subtraction; but unlike quantities can only be added or subtracted by placing the signs of these operations between them.

LIKE SIGNS, in Algebra, are the same signs, either both positive or both negative. But when one is positive and the other negative, they are unlike signs.

So, $+ 3ab$ and $+ 5cd$ have like signs,
as have also $- 2a^2c$ and $- 2ax^2$;
but $+ 3ab$ and $- 5cd$ have unlike signs,
as also $- 2ax$ and $3ax$.

LIKE FIGURES, or ARCS, &c, are the same as similar figures, arcs, &c. See *SIMILAR*. All like figures have their homologous lines in the same ratio. Also like plane figures are in the duplicate ratio, or as the squares of their homologous lines or sides; and like solid figures are in the

triplicate ratio, or as the cubes of their homologous lines or sides.

LILLY (WILLIAM), a noted English astrologer, born in Leicestershire in 1602. His father was not able to give him any farther education than common reading and writing; but young Lilly being of a forward temper, and endowed with shrewd wit, he resolved to push his fortune in London, where he arrived in 1620, and, for a present support, articled himself as a servant to a mantua-maker in the parish of St. Clement Danes. But in 1624 he moved a step higher, by entering into the service of Mr. Wright in the Strand, master of the Salters company, who not being able to write, Lilly among other offices kept his books. On the death of his master, in 1627, Lilly paid his addresses to the widow, whom he married with a fortune of 1000*l.* Being now his own master, he pursued the bent of his inclinations, which led him to follow the puritanical preachers; but afterwards, turning his mind to judicial astrology, in 1632 he became pupil, in that art, to one Evans, a profligate Welsh parson; and the next year gave the public a specimen of his skill, by an intimation that the king had chosen an unlucky horoscope for the coronation in Scotland. In 1634, getting a manuscript copy of the *Ars Noticia* of Cornelius Agrippa, with alterations, he followed the doctrine of the magic circle, and the invocation of spirits, with great eagerness, and practised it for some time; after which he treated the mystery of recovering stolen goods, &c with great contempt, claiming a supernatural sight, and the gift of prophetic predictions; all which he well knew how to turn to good advantage.

Mean while, he had buried his first wife, purchased a moiety of 13 houses in the Strand, and married a second wife, who, joining to an extravagant temper a termagant spirit, which, notwithstanding his skill in magic, he could not lay, made him unhappy, and greatly reduced his circumstances. With this uncomfortable yokemate he removed, in 1636, to Hersham in Surrey, where he staid till 1641; when, seeing a prospect of fishing in troubled waters, he returned to London. Here having purchased several curious books in this art, which were found on pulling down the house of another astrologer, he studied them incessantly, finding out secrets contained in them, which were written in an imperfect Greek character; and in 1644, published his *Merlinus Anglicus*, an almanac, which he continued annually till his death, and several other astrological works; devoting his pen, and other labours, sometimes to the king's party, and sometimes to that of the parliament, but mostly to the latter, raising his fortune by favourable predictions to both parties, sometimes by presents, and sometimes by pensions: thus, in 1648, the council of state gave him in money 50*l.* and a pension of 100*l.* per annum, which he received for two years, and then resigned it on some disgust. By his advice and contrivance, the king attempted several times to make his escape from his confinement: he procured and sent the aquaforts and files to cut the iron bars of his prison windows at Carisbrook castle; but still advising and writing for the other party at the same time. Mean while he read public lectures on astrology, in 1648 and 1649, for the improvement of young students in that art; and in short, plied his business so well, that in 1651 and 1652 he laid out near 2000*l.* for lands and a house at Hersham.

During the siege of Colchester, he and Booker were sent for thither, to encourage the soldiers; which they did by

assuring them that the town would soon be taken; which proved true in the event.—Having, in 1650, written publicly that the parliament should not continue, but a new government arise; agreeably to which, in his almanac for 1653, he asserted that the parliament stood upon a ticklish foundation, and that the commonalty and soldiery would join together against them. Upon which he was summoned before the committee of plundered ministers; but, receiving notice of it before the arrival of the messenger, he applied to his friend Lenthal the speaker, who pointed out the offensive passages. He immediately altered them; attended the committee next morning, with 6 copies printed, which six alone he acknowledged to be his; and by that means came off with only 13 days custody by the sergeant at arms. This year he was engaged in a dispute with Mr. Thomas Gataker.—In 1663 he was indicted at Hicks's-hall, for giving judgment on stolen goods; but was acquitted. And in 1659, he received from the king of Sweden, a present of a gold chain and medal, worth about 50*l.* on account of his having mentioned that n.onarch with great respect in his almanacs of 1657 and 1658.—After the Restoration, in 1660, being taken into custody, and examined by a committee of the house of commons, touching the execution of Charles the 1st, he declared, that Robert Spain, then secretary to Cromwell, dining with him soon after the fact, assured him it was done by cornet Joyce. The same year he sued out his pardon under the broad seal of England; and afterwards continued in London till 1665; when, on the raging of the plague there, he retired to his estate at Hersham. Here he applied himself to the study of physic, having, by means of his friend Elias Ashmole, procured from archbishop Sheldon a licence to practise it, which he did, as well as astrology, from thence till the time of his death.—In October 1666 he was examined before a committee of the house of commons concerning the fire of London, which happened in September that year. A little before his death, he adopted for his son, by the name of Merlin Junior, one Henry Coley, a taylor by trade; and at the same time gave him the impression of his almanac, which had been printed for 36 years successively. This Coley became afterwards a celebrated astrologer, publishing in his own name, almanacs, and books of astrology, particularly one entitled *A Key to Astrology*. Lilly died of a palsy in 1681, at 79 years of age; and his friend Mr. Ashmole placed a monument over his grave in the church of Walton-upon-Thames.

Lilly was author of many works. His Observations on the Life and Death of Charles late King of England, if we overlook the astrological nonsense, may be read with as much satisfaction as more celebrated histories; Lilly being not only very well informed, but strictly impartial. This work, with the Lives of Lilly and Ashmole, written by themselves, were published in one volume, 8vo, in 1774, by Mr. Burman. His other works were principally as follows: 1. *Merlinus Anglicus junior*.—2. *Supernatural Sight*.—3. *The White King's Prophecy*.—4. *England's Prophetic Merlin*: all printed in 1644.—5. *The Starry Messenger*, 1645.—6. *Collection of Prophecies*, 1646.—7. *A Comment on the White King's Prophecy*, 1646.—8. *The Nativities of Archbishop Laud and Thomas Earl of Strafford*, 1646.—9. *Christian Astrology*, 1647: on this piece he read his lectures in 1648, mentioned above.—10. *The Third book of Nativities*, 1647.—11. *The World's Catastrophe*, 1647.—12. *The Prophecies of Ambrose Mer-*

lin, with a Key, 1647.—13. Trithemius, or the Government of the World by Presiding Angels, 1647.—14. A treatise of the Three Suns seen in the winter of 1647, printed in 1648.—15. Monarchy or no Monarchy, 1651.—16. Observations on the Life and Death of Charles, late king of England, 1651; and again in 1651, with the title of Mr. William Lilly's True History of King James and King Charles the 1st, &c.—17. Annus Tenebrosus; or, the Black Year. This drew him into the dispute with Gataker, which Lilly carried on in his Almanac in 1654.

LIMB, the outermost border, or graduated edge, of a quadrant, astrolabe, or such like mathematical instrument. The word is also used for the arch of the primitive circle, in any projection of the sphere in plano.

LIMB also signifies the outermost border or edge of the sun or the moon; as the upper limb, or edge; the lower limb; the preceding limb, or side; the following limb.—Astronomers observe the upper or lower limb of the sun or moon, to find their true height, or that of the centre, which differs from the others by the semidiiameter of the disc.

LIMBERS, in Artillery, a sort of advanced train, joined to the carriage of a cannon on a march. It is composed of two shafts, wide enough to receive a horse between them, called the fillet horse: these shafts are joined by two bars of wood, and a bolt of iron at one end, and mounted on a pair of rather small wheels. On the axle-tree rises a strong iron spike, which is put into a hole in the hinder part of the train of the gun-carriage, to draw it by. But when a gun is in action, the limbers are taken off, and run out behind it.—See the dimensions and figure of it in Müller's Treatise of Artillery, pa. 187.

LIMIT, is a term used by mathematicians, for some determinate quantity, to which a variable one continually approaches, and may come nearer to it than by any given difference, but can never go beyond it; in which sense a circle may be said to be the limit of all its inscribed and circumscribed polygons: because these, by increasing the number of their sides, may be made to approach so near to the true area of the circle, that the difference shall be less than any assignable quantity.

LIMITS of the roots of EQUATIONS, in Algebra, form a part of that science, by means of which the solution of equations is sometimes much facilitated, particularly in those cases where we can only proceed by approximations; for, knowing that a root must lie between certain limits, that is, that it is greater than one known quantity, and less than another, we are led to a near approximate value in the first instance, which, without this consideration, we should have perhaps discovered only after a tedious operation.

To find a limit greater than the greatest root of an equation.

Let a , b , c , &c., be roots of an equation; transform it into another whose roots are $a - e$, $b - e$, $c - e$, &c.; and if by trial, such a value of e be found, that all the terms of the transformed equation be positive, all its roots are negative; and consequently e is greater than the greatest root of the proposed equation.

Suppose, for example, it were required to find a number greater than the greatest root of the equation $x^3 - 5x^2 + 7x - 1 = 0$.

Assume $x = y + e$, and we have

$$\begin{aligned} x^3 &= y^3 + 3y^2e + 3e^2y + e^3 \\ - 5x^2 &= - 5y^2 - 10ey - 5e^2 \\ + 7x &= + 7y + 7e \\ - 1 &= - 1 \end{aligned} = 0$$

in which equation, if 3 be substituted for e , each of the quantities $e^3 - 5e^2 + 7e - 1$, $3e^2 - 10e + 7$, $3e - 5$, is positive, or all the values of 7 are negative, therefore 3 is greater than the greatest value of x .

Again, to find a limit less than the least root of the equation $x^3 - 3x + 72 = 0$.

When the signs of these roots are changed, this equation becomes $x^3 - 3x - 72 = 0$.

Assume $x = y + e$, then

$$\begin{aligned} x^3 &= y^3 + 3y^2 + 3e^2y + e^3 \\ - 3x &= - 3y - 3e \\ - 72 &= - 72 \end{aligned} = 0$$

and here, if 5 be substituted for e , every term becomes positive, consequently 5 is greater than the greatest root of the equation $x^3 - 3x - 72 = 0$, and $- 5$ less than the least root of the equation $x^3 - 3x + 72 = 0$.

And in this manner may be found the limits of the roots of equations of any dimensions. For more on this subject, see Maclaurin's Algebra, and Wood's Algebra.

LIMIT of Distinct Vision, in Optics. See *Distinct VISION*.

LIMIT of a Planet, has been sometimes used for its greatest heliocentric latitude.

LIMITED Problem, denotes a problem that has but one solution, or some determinate number of solutions: as, to describe a circle through three given points that do not lie in a right line, which is limited to one solution only; to divide a parallelogram into two equal parts by a line parallel to one side, which admits of two solutions, according as the line is parallel to the length or breadth of the parallelogram; or to divide a triangle in any ratio by a line parallel to one side, which is limited to three solutions, as the line may be parallel to any of the three sides.

LINE, in Geometry, a quantity extended in length only, without either breadth or thickness. A line is sometimes considered as generated by the flux or motion of a point; and sometimes as the limit or termination of a superficies, but not as any part of that surface, however small.

Lines are either Right or Curved. A Right, or straight line, is the nearest distance between two points, which are its extremes or ends; or it is a line which has in every part of it the same direction or position. But a Curve Line has in every part of it a different direction, and is not the shortest distance between its extremes or ends.

Right Lines are all of the same species; but curves are of an infinite number of different sorts. As many may be conceived as there are different compound motions, or as many as there may be different relations between their ordinates, and abscissæ. See *CURVES*.

Again, *Curve Lines* are usually divided into geometrical and mechanical.

Geometrical Lines are those which may be found exactly in all their parts. See *GEOMETRICAL LINE*.

Mechanical Lines are such as are not determined exactly in all their parts, but only nearly, or tentatively.

Descartes, and his followers, define geometrical lines to be those which may be expressed by an algebraical equation of a determinate or finite degree, called its locus. And mechanical lines, such as cannot be expressed by such an equation. But others distinguish the same lines by the name Algebraical and Transcendental.

Lines are also divided into orders, by Newton, according to the number of intersections which may be made by them and a right line, viz. the 1st, 2d, 3d, 4th, &c., order, according as they may be cut by a right line, in 1, or 2, or 3, or 4, &c., points. In this way of considering them, the right line only is of the 1st order, being but one in

number; the 2d order contains 4 curves only, being such as may be cut from a cone by a plane, viz, the circle, the ellipse, the hyperbola, and the parabola; the lines of the 3d order have been enumerated by Newton, in a particular treatise, who makes their number amount to 72; but Mr. Stirling found 4 others, and Mr. Stone 2 more; though it is disputed by some whether the last two ought to be accounted different from some of Newton's, or not. See Newton's *Enumer. Lin. Tertiæ Ordin.* also Stirling's *Lineæ Tertiæ Ordin. Newtonianæ Oxon.* 1717, 8vo. and *Philos. Trans. No. 456, &c.* Again,

Algebraical Lines are divided into different orders according to the power or degree of their equations. So, the simple equation $a + by + cx = 0$, or equation of the 1st degree, denotes the 1st order or right line; the equation $a + by + cx + dy^2 + exy + fx^2 = 0$, of the 2d degree, denotes the lines of the 2d order; and the equation $a + by + cx + dy^2 + exy + fx^2 + gy^3 + hxy^2 + ix^2y + hx^3 = 0$, of the 3d degree, expresses the lines of the 3d order; and so on. See Cramer's *Introduct. à l'Analyse des Lignes Courbes.*

Lines, considered with regard to their positions, are either Parallel, Perpendicular, or Oblique. The construction of which, see under the respective terms.

LINE also denotes a French measure of length, being the 12th part of an inch, or the 144th part of a foot.

In *Astronomy*,

LINE of the Apses, or Apsides, the line joining the two apses, or the longer axis of the orbit of a planet.

Fiducial Line, the index line or edge of the ruler, which passes through the middle of an astrolabe, or other instrument, on which the sights are fitted, and marking the divisions.

Horizontal Line, a line parallel to the horizon.

LINE of the Nodes, that which joins the nodes of the orbit of a planet, being the common section of the plane of the orbit with the plane of the ecliptic.

In *Dialling*,

Horizontal Line, is the common section of the horizon and the dial-plate.

Horary, or Hour Lines, are the common intersections of the hour-circles of the sphere with the plane of the dial.

Equinoctial Line, is the common intersection of the equinoctial and the plane of the dial.

In *Fortification*, Line is sometimes used for a ditch, bordered with its parapet; and sometimes for a row of gabions, or sacks of earth, extended lengthwise on the ground, to serve as a shelter against the enemy's fire. When the trenches have been carried on within 30 paces of the glacis, they draw two lines, one on the right, and the other on the left, for a place of arms.

Lines are commonly made to shut up an avenue or entrance to some place; the sides of the entrance being covered by rivers, woods, mountains, morasses, or other obstructions, not easy to be passed over by an army. When they are constructed in an open country, they are carried round the place to be defended, and resemble the lines surrounding a camp, called lines of circumvallation. Lines are also thrown up to stop the progress of an army; but the term is mostly used for the line covering a pass which can only be attacked in front.

When lines are made to cover a camp, or a large tract of land, where a considerable body of troops is posted, the work is not made in one straight, or uniformly bending line; but, at certain distances, the lines project in

salient angles, called redents, redans, or flankers, towards the enemy. The distance between these angles is commonly between the limits of 200 and 260 yards; the ordinary flight of a musket ball, point blank, being commonly within those limits; though muskets a little elevated will do effectual service at the distance of 360 yards.

Fundamental Line, is the first line drawn for the plan of a place, and which shows its area.

Central Line, is the line drawn from the angle of the centre to the angle of the bastion.

Line of Defence, &c. See DEFENCE, &c.

Line of Approach, or Attack, signifies the work which the besiegers carry on under cover, to gain the moat, and the body of the place.

Line of Circumvallation, is a line or trench cut by the besiegers, within cannon-shot of the place, ranging round the camp, and securing its quarters against any relief to be brought to the besieged.

Line of Contravallation, is a ditch bordered with a parapet, serving to cover the besiegers on the side next the place, and to stop the sallies of the garrison.

Lines of Communication are those which run from one work to another.

Line of the Base, is that which joins the points of the two nearest bastions.

To Line a work, signifies to face it, as with brick or stone; for example, to strengthen a rampart with a firm wall, or to encompass a parapet or moat with good turf, &c.

LINE, in Geography and Navigation, is emphatically used for the equator or equinoctial line.

In *Perspective*,

The Geometrical Line, is a right line drawn in any manner on the geometrical plane.

Terrestrial or Fundamental Line, is the common intersection of the geometrical plane and plane of the picture.

Line of the Front, is any line parallel to the terrestrial line.

Vertical Line, is the section of the vertical and draft planes.

Visual Line, is the line or ray conceived to pass from the object to the eye.

Objective Line, is any line drawn on the geometrical plane, whose representation is sought for in the draught or picture.

Line of Measures, is used by Oughtred, and others, to denote the diameter of the primitive circle, in the projection of the sphere in plano, or that line in which falls the diameter of any circle to be projected.

LINEAR NUMBERS, are such as have relation to length only; such, for example, as express one side of a plane figure; and when the plane figure is a square, the linear number is called a root.

LINEAR PROBLEM, is one that can be solved geometrically by the intersection of two right lines. This is called a simple problem, and is capable of only one solution.

Liquid, a fluid which wets or smears such bodies as are immersed in it, arising from some configuration of its particles, which disposes them to adhere to the surfaces of bodies contiguous to them. Thus, water, oil, milk, &c., are liquids, as well as fluids; but quicksilver is not a liquid, but simply a fluid.

LISLE (WILLIAM DE), a learned French geographer, was born at Paris in 1675. His father being much occu-

pied in the same pursuit, young Lisle began at 9 years of age to draw maps, and soon made a considerable progress in this art. In 1699 he first distinguished himself to the public, by giving a map of the world, and other pieces, which procured him a place in the Academy of Sciences, 1702. He was afterwards appointed geographer to the king, with a pension, and had the honour of instructing the king himself in geography, for whose particular use he drew up several works. Delisle's reputation was so great, that scarcely any history or travels came out without the embellishment of his maps. Nor was his name less celebrated abroad than in his own country. Many sovereigns in vain attempted to draw him out of France. The Czar Peter, when at Paris on his travels, paid him a visit, to communicate to him some remarks upon Muscovy; but more especially, says Fontenelle, to learn from him, better than he could any-where else, the extent and situation of his own dominions. Delisle died of an apoplexy in 1726, at 51 years of age. Besides the excellent maps he published, he wrote many pieces in the Memoirs of the Academy of Sciences.

LISLE (JOSEPH-NICHOLAS DE), an eminent astronomer and geographer, was born at Paris in 1688. He was brother of the above-mentioned William, and had the same education with him under their father, in geography and astronomy. At the age of 18 he made an accurate observation of the great total eclipse of the sun in 1706; which may be considered as the beginning of his public career. He was admitted in the astronomical department of the Academy in 1714. In 1724 he visited England, and was much esteemed by Newton and Halley; and he was also chosen a Fellow of the Royal Society. In 1726 he was invited to Petersburg, where he had the charge of the observatory, with a considerable pension. He returned to Paris in 1747, where he filled the place of professor to the Royal College, and where he formed the astronomers Laland and Messier, illustrious pupils of so great a master. M. Delisle died in 1768. His principal works are, his History of Astronomy, 1738, in 2 vols 4to; and 44 memoirs in the volumes of the Academy, from the year 1714 to 1766.

LIST, or LISTEL, a small square moulding, serving to crown or accompany larger mouldings; or on occasion to separate the flutings of columns.

LITERAL ALGEBRA. See ALGEBRA.

LIZARD, in Astronomy. See LACERTA.

LOADSTONE, or MAGNET; which see.

LOCAL Problem, is one that is capable of an infinite number of different solutions; because the point, which is to solve the problem, may be indifferently taken within a certain extent; as suppose any-where in such a line, within such a plane figure, &c, which is called a Geometrical Locus.

A local problem is Simple, when the point sought is in a right line; Plane, when the point sought is in the circumference of a circle; Solid, when it is in the circumference of a conic section; or Sursolid, when the point is in the perimeter of a line of a higher kind.

LOCAL MOTION, or *Loco-Motion*, the change of place: See MOTION.

LOCI, the plural of LOCUS, which see.

LOCI PLANI, or *Loca Plana*, one of the last works of Apollonius, that have been restored by Schooten, in 1656; by Fermat, in 1679; and by Simson, in 1749.

LOCK, for Canals. See CANAL.

LOCUS, is some line by which a local or indeterminate problem is solved; or a line of which any point may equally solve an indeterminate problem. Loci are expressed by algebraic equations of different orders, according to the nature of the locus. If the equation is constructed by a right line, it is called Locus ad Rectum; if by a circle, Locus ad Circulum; if by a parabola, Locus ad Parabolam; if by an ellipsis, Locus ad Ellipsim; and so on.

The loci of such equations as are right lines or circles, the ancients called Plane Loci; and of those that are conic sections, Solid Loci; but such as are curves of a higher order, Sursolid Loci. The moderns distinguish the loci into orders according to the dimensions of the equations by which they are expressed, or the number of the powers of indeterminate or unknown quantities in any one term: thus, the equation

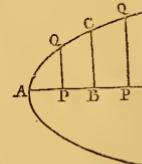

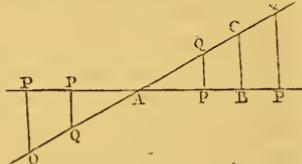

$ay = bx + c$ denotes a locus of the 1st order, but $y^2 = ax$, or $= ax - x^2$, &c, a locus of the 2d order, and $y^3 = a^2x$, or $= ax^2 - x^3$, &c, a locus of the 3d order, and so on; where x and y are unknown or indeterminate quantities, and the others known or determinate ones; also x denotes the absciss, and y the ordinate of the curve or line which is the locus of the equation.

For instance, suppose two variable or indeterminate

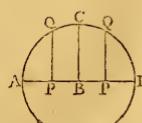

right lines AP , AQ , making any given angle $\angle PAQ$ between them, where they are supposed to commence, and to extend indefinitely both

ways from the point A : then calling any AP , x , and its corresponding ordinate PQ , y , continually changing its position by moving parallel to itself along the indefinite line AP ; also in the line AP assume $AB = a$, and from B draw BC parallel to PQ and $= b$: then the indefinite line AQ is called in general a Geometrical Locus, and in particular the locus of the equation $y = \frac{bx}{a}$; for whatever point Q is, the triangles $\triangle ABC$, $\triangle APQ$ are always similar, and therefore $AB : BC :: AP : PQ$, that is $a : b :: x : y$, therefore $ay = bx$ is the equation to the right line AQ , or AQ is the locus of the equation $ay = bx$.

Again, if AQ be a parabola, the nature of which is such, that $AB : AP :: BC : PQ^2$, or $a : x :: b^2 : y^2$, and therefore $ay^2 = b^2x$ is the equation which has the parabola for its locus, or the parabola is the locus to every equation of this form $ay^2 = b^2x$.

Or if AQ be a circle, having its radius $AB = a$, the nature of which is this, that $PQ^2 = AP \cdot PD$, or $y^2 = x \cdot (2a - x)$ or $= 2ax - x^2$; therefore the locus of the equation of this form $y^2 = 2ax - x^2$, is a circle.

In like manner it will appear, that the ellipse is the locus to the equation $\ell^2y^2 = c^2 \times (tx - x^2)$, and the hyperbola the locus to the equation $\ell^2y^2 = c^2 \times (tx + x^2)$; where ℓ is the transverse, and c the conjugate axis of the ellipse or hyperbola.

All equations whose loci are of the first order, may be reduced to one of the 4 following forms: 1st, $y = \frac{tx}{a}$; 2d, $y = \frac{tx}{a} + c$; 3d, $y = \frac{tx}{a} - c$; 4th, $y = c - \frac{tx}{a}$; where the letter c denotes the distance that the ordinates commence from the line AP , either on the one side or the other of it, according as the sign of that quantity is + or -.

All loci of the 2d degree are conic sections, viz, either the parabola, the circle, ellipsis, or hyperbola. Therefore when an equation is given, whose locus is of the 2d degree, and it is required to draw that locus, or, which is the same thing, to construct the equation generally; bring over all the terms of the equation to one side, so that the other side be 0; then to know which of the conic sections it denotes, there will be two general cases, viz, either when the rectangle xy is in the equation, or when it is not in it.

Case 1. When the term xy is not in the proposed equation. Then, 1st, if only one of the squares x^2, y^2 be found in it, the locus will be a parabola. 2d, If both the squares be in it, and if they have the same sign, the locus will be a circle or an ellipsis. 3d, But if the signs of the squares x^2, y^2 be different, the locus will be an hyperbola, or the opposite hyperbolas.

Case 2. When the rectangle xy is in the proposed equation; then 1st, If neither of the squares x^2, y^2 , or only one of them be in the equation, the locus will be an hyperbola between the asymptotes. 2d, If both x^2 and y^2 be in it, having different signs, the locus will be an hyperbola, having the abscissæ on its diameter. 3d, If both the squares be in it, and with the same sign, then if the coefficient of x^2 be greater than the square of half the coefficient of xy , the locus will be an ellipse; if equal, a parabola; and if less, an hyperbola.

This method of determining geometric loci, by reducing them to the most compound or general equations, was first published by Mr. Craig, in his *Treatise on the Quadrature of Curves*, in 1693. It is explained at large in the 7th and 8th books of l'Hospital's *Conic Sections*. This subject is also particularly illustrated in Maclaurin's *Algebra*. The method of Descartes for finding the loci of equations of the 2d order, is by extracting the root of the equation. See his *Geometry*; as also Stirling's *Illustratio Linearum Tertiæ Ordinis*. The doctrine of these loci is likewise well treated by De Witt in his *Elementa Curvarum*. And Bartholomæus Intieri, in his *Aditus ad Nova Arcana Geometrica delegenda*, has shown how to find the loci of equations of the higher orders. Mr. Stirling too, in his treatise above-mentioned, has given an example or two of finding the loci of equations of 3 dimensions. Euclid, Apollonius, Aristæus, Fermat, Viviani, have also written on the subject of loci.

LOG, in Navigation, is a piece of thin board, of a sectoral or quadrant form, loaded in the circular side with lead sufficient to make it swim upright in the water; to which is fastened a line of about 150 fathoms, or 300 yards long, called the log-line, divided into certain spaces, called knots, and wound on a reel turning very freely, for the line to wind easily off.

The use of the log, or log-line, is to measure the velocity of the ship, or rate at which she runs, which is done from time to time, as the foundation on which the ship's reckoning, or finding her place, is kept; and the practice is, to heave the log into the sea, with the line tied to it, and by observing how much of the line is run off the reel, while the ship sails, during the space of half a minute, which time is measured by a sand-glass made to run that time very exactly. About 10 fathoms of stray or waste line is left next the log before the knotting or counting commence, that space being usually allowed to carry the log out of the eddy of the ship's wake.

The using of the log for finding the velocity of the ship, is called heaving the log, and is thus performed: One man holds the reel, and another the half-minute glass; an officer of the watch throws the log over the ship's stern, on the lee-side, and when he observes the stray line, and the first mark is going off, he cries Turn! when the glass-holder instantly turns the glass crying out Done! then watching the glass, the moment it is run out he says Stop! upon which the reel being quickly stopt, the last mark run off shows the number of knots, and the distance of that mark from the reel is estimated in fathoms: then the knots and fathoms together show the distance run in half a minute, or the distance per hour nearly, by considering the knots as miles, and the fathoms as decimals of a mile: Thus, if 7 knots and 4 fathoms be observed, then the ship runs at the rate of 7·4 miles an hour.

It follows, therefore, that the length of each knot, or division of the line, ought to be the same part of a sea mile, as half a minute is of an hour, that is $\frac{1}{120}$ th part. Now it is found that a degree of the meridian contains nearly 366,000 feet, therefore $\frac{1}{120}$ th of this, or a nautical mile, will be 6100 feet; the $\frac{1}{120}$ th of which, or 51 feet nearly, should be the length of each knot, or division of the log-line. But, because it is safer to have the reckoning rather before the ship, than after it, it is therefore usual now to make each knot equal to 8 fathoms or 48 feet. But the knots are made sometimes to contain only 42 feet; which method of dividing the log-line is founded on the supposition, that 60 miles, of 5000 feet each, make a degree; for $\frac{1}{120}$ th of 5000 is $41\frac{2}{3}$, or in round numbers 42 feet. And though many mariners find by experience that this length of the knot is too short, yet rather than quit the old way, they use sand-glasses for half-minute ones that run only 24 or 25 seconds. The sand, or half-minute glass, may be tried by a pendulum vibrating seconds, in the following manner: On a hook or peg, hang a thread or fine string that has a musket-ball fixed to one end, carefully measuring between the centre of the ball and the string's loop over the nail $39\frac{1}{2}$ inches, being the length of a second pendulum; then make it swing or vibrate very small arches, and count one for every time it passes under the nail, beginning at the second time it passes; and the number of swings made during the time the glass is running out, shows the seconds in the glass.

It is not known who was the inventor of this method of measuring the ship's way, or her rate of sailing; but no mention of it occurs till the year 1607, in an East-India voyage, published by Purchas; and from that time its name occurs in other voyages in his collections; after which it became more known, being noticed both by our own authors, and by foreigners; as by Gunter in 1623; Snellius, in 1624; Metius, in 1631; Oughtred, in 1633; Herigone, in 1634; Saltonstall, in 1636; Norwood, in

1637; Fournier, in 1643; and almost all the succeeding writers on navigation of every country. Various improvements have lately been made on this instrument by different persons. See Robertson's Navigation, the Preface, pa. v. Also Hist. Math. tom. iv, 525—537.

Log-Board, in Navigation, a board or table usually divided into 5 columns: in the first of which is entered the hour of the day; in the 2d, the course steered; in the 3d, the number of knots run off the reel each time of heaving the log; in the 4th, the direction of the wind; and in the 5th, observations on the weather, variation of the compass, &c.

Log-Book, a book ruled in columns like the log-board, into which the account on this is transcribed every day at noon; from whence, after it is corrected, &c, it is entered into the journal.

LOGARITHM, from the Greek λογισμός ratio, and αριθμός number; q. d. ratio of numbers, or perhaps rather number of ratios; the indices of the ratios of numbers to one another; or a series of numbers in arithmetical proportion, corresponding to as many others in geometrical proportion, in such sort that 0 corresponds to, or is the index of 1, in the geometricals. They have been devised for the ease of large arithmetical calculations.

Thus,

0	1	2	3	4	&c, indices or logarithms.
1	2	4	8	16	&c,
or 2 ⁰	2 ¹	2 ²	2 ³	2 ⁴	&c, the geometrical
1	3	9	27	81	&c, progressions, or
or 3 ⁰	3 ¹	3 ²	3 ³	3 ⁴	&c, common num-
1	10	100	1000	10000	bers.
or 10 ⁰	10 ¹	10 ²	10 ³	10 ⁴	&c,

Where the same indices, or logarithms, serve equally for any geometric series; and from which it is evident, that there may be an endless variety of sets of logarithms to the same common numbers, by varying the 2d term 2, or 3, or 10, &c, of the geometric series; as this will change the original series of terms whose indices are the numbers 1, 2, 3, &c; and, by interpolation, the whole system of numbers may be made to enter the geometrical series, and receive their proportional logarithms, whether integers or decimals.

Or the logarithm of any given number, is the index of such a power of some other number, as is equal to the given one. So if n be r^n , then the logarithm of n is n , which may be either positive or negative, and r any number whatever, according to the different systems of logarithms. When n is 1, then n is r ; consequently the root r is always the number whose logarithm is 1, in every system. When $r = 2718281828459$ &c, the indices are the hyperbolic logarithms; so that n is always the hyperbolic logarithm of $(2718 \dots)^n$. But in the common logarithms $r = 10$; so that the common logarithm of any number, is the index of that power of 10 which is equal to the said number; so the common logarithm of $n = 10^x$, is x the index of the power of 10; for example, 1000, being the 3d power of 10, has 3 for its logarithm; and if 50 be $10^{1.69897}$, then is 1.69897 the common logarithm of 50. And hence it follows that this decimal series of terms

VOL. I.

1000, 100, 10, 1, .1, .01, .001,
or $10^3, 10^2, 10^1, 10^0, 10^{-1}, 10^{-2}, 10^{-3}$,
have 3, 2, 1, 0, -1, -2, -3,
respectively for the logarithms of those terms.

The logarithm of a number contained between any two terms of the first series, is included between the two corresponding terms of the latter; and therefore that logarithm will consist of the same index, whether positive or negative, as the smaller of those two terms, together with a decimal fraction, which will always be positive. So the number 50 falling between 10 and 100, its logarithm will fall between 1 and 2, being indeed equal to 1.69897 nearly: also the number .05 falling between the terms 1 and .01, its logarithm will fall between -1 and -2, and is indeed = -2 + .69897, the index of the less term together with the decimal .69897. The index is also called the characteristic of the logarithms, and is always an integer, either positive or negative, or else = 0; and it shows what place is occupied by the first significant figure of the given number, either above or below the place of units, being in the former case + or positive; in the latter — or negative.

When the index of a logarithm is negative, the sign — is commonly set over it, to distinguish it from the decimal part, which, being the logarithm found in the tables, is always positive: so $-2 + .69897$, or the logarithm of .05, is written thus $\bar{2}.69897$. But on some occasions it is convenient to reduce the whole expression to a negative form; which is done by making the characteristic less by 1, and taking the arithmetical complement of the decimal, that is, beginning at the left hand, subtract each figure from 9, except the last significant figure, which is subtracted from 10; so shall the remainders form the logarithm wholly negative: thus the logarithm of .05, which is $\bar{2}.69897$ or $-2 + .69897$, is also expressed by -1.30103 , which is all negative. It is also sometimes thought more convenient to express such logarithms entirely as positive, namely by only joining to the tabular decimal the complement of the index to 10; and in this way the above logarithm is expressed by 8.69897 ; which is only increasing the indices in the scale by 10.

The Properties of Logarithms.—From the definition of logarithms, either as being the indices of a series of geometricals, or as the indices of the power of the same root, it follows, that the multiplication of the numbers will answer to the addition of their logarithms; the division of numbers, to the subtraction of their logarithms; the raising of powers, to the multiplying the logarithm of the root by the index of the power; and the extracting of roots, to the dividing the logarithm of the given number by the index of the root required to be extracted.

So, 1st,

Log. ab or of $a \times b$ is = log. $a + \log. b$,

Log. 18 or of 3×6 is = log. $3 + \log. 6$,

Log. $5 \times 9 \times 73$ is = log. $5 + \log. 9 + \log. 73$.

Secondly,

Log. $a \div b$ is = log. $a - \log. b$,

Log. $18 \div 6$ is = log. $18 - \log. 6$,

Log. $79 \times 5 \div 9$ is = log. $79 + \log. 5 - \log. 9$,

Log. $\frac{1}{2}$ or $1 \div 2$ is = $1.1 - 1.2 = 0 - 1.2 = -1.2$,

Log. $\frac{1}{n}$ or $1 \div n$ is = $1.1 - 1.n = -1.n$.

5 C

Thirdly,

$$\text{Log. } r^n \text{ is } = n \text{ l. } r; \text{ log. } r^{\frac{1}{n}} \text{ or of } \sqrt[n]{r} \text{ is } = \frac{1}{n} \text{ l. } r;$$

$$\text{Log. } r^{\frac{m}{n}} \text{ is } = \frac{m}{n} \text{ l. } r; \text{ log. } 2^6 \text{ is } = 6 \text{ l. } 2; \text{ log. } 2^{\frac{2}{3}} \text{ or}$$

$$\text{of } \sqrt[3]{2} \text{ is } = \frac{1}{3} \text{ l. } 2; \text{ and log. } 2^{\frac{2}{3}} \text{ is } = \frac{2}{3} \text{ l. } 2.$$

So that any number and its reciprocal have the same logarithm, but with contrary signs; and the sum of the logarithms of any number and its reciprocal, or complement, is equal to 0. For other particulars, see the Introduction to my Logarithms.

History and Construction of Logarithms.—The properties of logarithms hitherto mentioned, or of arithmetical indices to powers or geometricals, with their various uses and properties, as above-mentioned, are taken notice of by Stifelius, in his Arithmetic; and indeed they were not unknown to the ancients; but they come all far short of the use of logarithms in trigonometry, as first discovered by John Napier, baron of Merchiston in Scotland, and published at Edinburgh in 1614, in his Mirifici Logarithmorum Canonis Descriptio; which contained a large canon of logarithms, with the description and uses of them; but their construction was reserved till the sense of the learned concerning his invention should be known. This work was translated into English by the celebrated Mr. Edward Wright, and published by his son in 1616. In the year 1619, Robert Napier, son of the inventor of logarithms, published a new edition of his late father's work, together with the promised construction of the logarithms, with other miscellaneous pieces written by his father and Mr. Briggs. And in the same year, 1619, Mr. John Speidell published his New Logarithms, being an improved form of Napier's.

All these tables were of the kind that have since been called hyperbolical, because the numbers express the areas between the asymptote and curve of the hyperbola. And logarithms of this kind were also soon after published by several other persons; as by Ursinus in 1619, Kepler in 1624, and some others.

On the first publication of Napier's logarithms, Henry Briggs, then professor of geometry in Gresham-college in London, immediately applied himself to the study and improvement of them, and soon published the logarithms of the first 1000 numbers, but on a new scale, which he had invented, viz., in which the logarithm of the ratio of 10 to 1 is 1, the logarithm of the same ratio in Napier's system being 2.30258 &c.; and in 1624, Briggs published his Arithmetica Logarithmica, containing the logarithms of 30,000 natural numbers, to 14 places of figures besides the index, in a form that Napier and he had agreed upon together, being the present form of logarithms; also in 1633 was published, to the same extent of figures, his Trigonometria Britannica, containing the natural and logarithmic sines, tangents, &c.

With various and gradual improvements, logarithms were also published successively, by Gunter in 1620, Wingeate in 1624, Henrion in 1626, Miller and Norwood in 1631, Cavalierius in 1632 and 1643, Vlaeq and Rowe in 1633, Frobenius in 1634, Newton in 1658, Caramuel in 1670, Sherwin in 1706, Gardiner in 1742, and Dodson's Antilogarithmic Canon in the same year, Taylor in 1793, besides many others of lesser note; not to mention the accurate and comprehensive tables in the Tables Portative in 1793, &c., those of Borda and Delambre in 1801, and

in my own Logarithms lately published, where a complete history of this science may be seen, with the various ways of constructing them, that have been invented by different authors.

In Napier's construction of logarithms, the natural numbers, and their logarithms, as he sometimes called them, or at other times the artificial numbers, are supposed to arise, or to be generated, by the motions of points, describing two lines, of which the one is the natural number, and the other its logarithm, or artificial. Thus, he conceived the line or length of the radius to be described, or run over, by a point moving along it in such a manner, that in equal portions of time it generated, or cut off, parts in a decreasing geometrical progression, leaving the several remainders, or sines, in geometrical progression also; while another point described equal parts of an indefinite line, in the same equal portions of time; so that the respective sums of these, or the whole line generated, were always the arithmetical or logarithms of the aforesaid natural sines. In this idea of the generation of the logarithms and numbers, Napier assumed 0 as the logarithm of the greatest sine or radius; and next he limited his system, not by assuming a particular value to some assigned number, or part of the radius, but by supposing that the two generating points, which, by their motions along the two lines, described the natural numbers and logarithms, should have their velocities equal at the beginning of those lines. And this is the reason that, in his table, the natural sines and their logarithms, at the complete quadrant, have equal differences or increments; and this is also the reason why his scale of logarithms happens accidentally to agree with what have since been called the hyperbolical logarithms, which have likewise numeral differences equal to those of their natural numbers at the beginning; except only that these latter increase with the natural numbers, while his on the contrary decrease; the logarithm of the ratio of 10 to 1 being the same in both, namely 2.30258509 &c.

Having thus limited his system, Napier proceeds, in the posthumous work of 1619, to explain his construction of the logarithmic canon. This he effects in various ways, but chiefly by generating, in a very easy manner, a series of proportional numbers, and their arithmetical or logarithms; and then finding, by proportion, the logarithms to the natural sines from those of the natural numbers, among the original proportionals; a particular account of which may be seen in my book of logarithms above mentioned.

The methods above alluded to, relate to Napier's or the hyperbolical system of logarithms, and indeed are in a manner peculiar to that kind of them. But in an appendix to the posthumous work, mention is made of other methods, by which the common logarithms, agreed on by him and Briggs, may be constructed, and which it appears were written after that agreement. One of these methods is as follows: Having assumed 0 for the logarithm of 1, and 10000 &c., for the logarithm of 10; this logarithm of 10, and the successive quotients, are to be divided ten times by 5, by which divisions there will be obtained these other ten logarithms, namely 2000000000, 400000000, 80000000, 16000000, 3200000, 640000, 128000, 25600, 5120, 1024; then this last logarithm, and its quotients, being divided ten times by 2, will give these other ten logarithms,

viz, 512, 256, 128, 64, 32, 16, 8, 4, 2, 1.

Also the numbers answering to these twenty logarithms are to be found in this manner, viz, Extract the 5th root of 10 (with ciphers), then the 5th root of that root, and so on for ten continual extractions of the 5th root: so shall these ten roots be the natural numbers belonging to the first ten logarithms above found, in dividing continually by 5. Next, out of the last 5th root is to be extracted the square root, then the square root of this last root, and so on for ten successive extractions of the square root: so shall these last ten roots be the natural numbers corresponding to the logarithms or quotients arising from the last ten divisions by the number 2. And from these twenty logarithms, 1, 2, 4, 8, &c, and their natural numbers, the author observes that other logarithms and their numbers may be formed, namely by adding the logarithms, and multiplying their corresponding numbers. But, besides the immense labour of this method, it is evident that this process would generate rather an antilogarithmic canon, such as Dodson's, than the table of Briggs.

Napier next mentions another method of deriving a few of the primitive numbers and their logarithms, namely, by taking continually geometrical means, first between 10 and 1, then between 10 and this mean, and again between 10 and the last mean, and so on; and then taking the arithmetical means between their corresponding logarithms.

He then lays down various relations between numbers and their logarithms, such as, that the products and quotients of numbers, answer to the sums and differences of their logarithms; and that the powers and roots of numbers, answer to the products and quotients of the logarithms when multiplied or divided by the index of the power or root, &c; as also that, of any two numbers, whose logarithms are given, if each number be raised to the power denoted by the logarithm of the other, the two results will be equal; thus, if x be the logarithm of any number x , and y the logarithm of y , then is $x^y = y^x$. Napier then advertises to another method of making the logarithms to a few of the prime integer numbers, which is well adapted for the construction of the common table of logarithms: this method easily follows from what has been said above, depending on this property, that the logarithm of any number, in this scale, is one less than the number of places or figures contained in that power of the given number whose exponent is 10000000000, or the logarithm of 10, at least as to integer numbers, for they really differ by a fraction, as is shown by Mr. Briggs in his illustrations of these properties; printed at the end of the Appendix to the Construction of Logarithms.

Kepler gave a construction of logarithms somewhat varied from Napier's. His work is divided into two parts: In the first, he raises a regular and purely mathematical system of proportions, and the measures of them, demonstrating both the nature and principles of the construction of logarithms, which he calls the Measures of Ratios: and in the second part, he applies those principles in the actual construction of his table, which contains only 1000 numbers and their logarithms. The fundamental principles are briefly these: That at the beginning of the logarithms, their increments or differences are equal to those of the natural numbers: that the natural numbers may be considered as the decreasing cosines of increasing arcs: and that the secants of those arcs at the beginning have the same differences as the cosines, and therefore the

same differences as the logarithms. Then, since the secants are the reciprocals of the cosines of the same arcs, from the foregoing principles, he establishes the following method of raising the first 100 logarithms, to the numbers 1000, 999, 998, &c, to 900; viz, in this manner: Divide the radius 1000, increased with seven ciphers, by each of these numbers separately, and the quotients will be the secants of those arcs which have the divisors for their cosines; continuing the division to the 8th figure, as it is in that place only that the arithmetical and geometrical means differ. Then by adding continually the arithmetical means between every two successive secants, the sums will be the series of logarithms. Or by adding continually every two secants, the successive sums will be the series of the double logarithms. He then derives all the other logarithms from these first 100, by common principles.

Briggs first advertes to the methods mentioned above, in the Appendix to Napier's Construction, which methods were common to both these authors, and had doubtless been jointly agreed on by them. He then gives an example of computing a logarithm by the property, that the logarithm is one less than the number of places or figures contained in that power of the given number whose exponent is the logarithm of 10 with ciphers. Briggs next treats of the other general method of finding the logarithms of prime numbers, which he thinks is an easier way than the former, at least when many figures are required. This method consists in taking a great number of continued geometrical means between 1 and the given number whose logarithm is required; that is, first extracting the square root of the given number, then the root of the 1st root, the root of the 2d root, the root of the 3d root, and so on, till the last root shall exceed 1 by a very small decimal, greater or less according to the intended number of places to be in the logarithm sought: then finding the logarithm of this small number, by easy methods described afterwards, he doubles it as often as he made extractions of the square root, or, which is the same thing, he multiplies it by such power of 2 as is denoted by the said number of extractions, and the result is the required logarithm of the given number; as is evident from the nature of logarithms.

But, as the extraction of so many roots is a very troublesome operation, our author devises some ingenious methods of abridging that labour, chiefly by a proper application of the several orders of the differences of numbers, forming the first instance of what may be called The Differential Method; for a particular description of which, see my Logarithms, above quoted, pa. 65, &c.

Mr. James Gregory, in his *Vera Circuli Hyperbolae Quadratura*, printed at Padua in 1667, having approximated to the hyperbolic asymptotic spaces by means of a series of inscribed and circumscribed polygons, from thence shows how to compute the logarithms, which are analogous to the areas of those spaces; and thus the quadrature of the hyperbolic spaces became the same thing as the computation of the logarithms. He here also lays down various methods to abridge the computation, with the assistance of some properties of numbers themselves, by which the logarithms of all prime numbers under 1000 may be computed, each by one multiplication, two divisions, and the extraction of the square root. And the same subject is further pursued in his *Exercitationes Geometricae*. In this latter place, he first finds an algebraic expression, in an infinite

series, for the logarithm of $\frac{1+a}{1}$, and then likewise for the logarithm of $\frac{1}{1-a}$; and as the one series has all its terms positive, while those of the other are alternately positive and negative, by adding the two together, every 2d term is cancelled, and the double of the other terms gives the logarithm of the product of $\frac{1+a}{1}$ and $\frac{1}{1-a}$, or the logarithm of $\frac{1+a}{1-a}$, that is, of the ratio of $1-a$ to $1+a$:

Thus, he finds,

$$\text{first } a - \frac{1}{2}a^2 + \frac{3}{4}a^3 - \frac{1}{4}a^4 \&c = \log. \text{ of } \frac{1+a}{1},$$

$$\text{and } a + \frac{1}{2}a^2 + \frac{3}{4}a^3 + \frac{1}{4}a^4 \&c = \log. \text{ of } \frac{1}{1-a}.$$

$$\text{theref. } 2a + \frac{3}{2}a^3 + \frac{3}{2}a^5 + \frac{3}{2}a^7 \&c = \log. \text{ of } \frac{1+a}{1-a}.$$

Which may be accounted Mr. James Gregory's method of making logarithms.

In 1668, Nicholas Mercator published his Logarithmetria, sive Methodus Construendi Logarithmos, nova, accurata, et facilis; in which he delivers a new and ingenious method for computing the logarithms on principles purely arithmetical; and here, in his modes of thinking and expression, he closely follows the celebrated Kepler, in his writings on the same subject; accounting logarithms as the measures of ratios, or as the number of ratiunculae contained in the ratio which any number bears to unity. Purely from these principles then, the number of the equal ratiunculae contained in some one ratio, as of 10 to 1, being supposed given, our author shows how the logarithm, or measure, of any other ratio may be found. But this, however, only by-the-bye, as not being the principal method he intends to teach, as his last and best. Having shown then, that these logarithms, or numbers of small ratios, or measures of ratios, may be all properly represented by numbers, and that of 1, or the ratio of equality, the logarithm or measure being always 0, the logarithm of 10, or the measure of the ratio of 10 to 1, is most conveniently represented by 1 with any number of ciphers; he then proceeds to show how the measures of all other ratios may be found from this last supposition: and he explains these principles by some examples in numbers.

In the latter part of the work, Mercator treats of his other method, given by an infinite series of algebraic terms, which are collected in numbers by common addition only. He here squares the hyperbola, and finally finds that the hyperbolic logarithm of $1+a$, is equal to the infinite series $a - \frac{1}{2}a^2 + \frac{1}{2}a^3 - \frac{1}{4}a^4 \&c$; which may be considered as Mercator's quadrature of the hyperbola, or his general expression of an hyperbolic logarithm, in an infinite series.

And this method was further improved by Dr. Wallis, in the Philos. Trans. for the year 1668; by showing that the hyp. log. of the ratio of 1 to $1-a$ is equal to the infinite series $a + \frac{1}{2}a^2 + \frac{3}{4}a^3 + \frac{1}{4}a^4 + \&c$. The celebrated Newton invented also the same series for the quadrature of the hyperbola, and the construction of logarithms, and that before they were given by Gregory and Mercator, though unknown to one another, as appears by his letter to Mr. Oldenburg, dated October 24, 1676. The explanation and construction of the logarithms are also further pursued in his Fluxions, published in 1736 by Mr. Colson.

Dr. Halley, in the Philos. Trans. for the year 1695,

gave a very ingenious essay on the construction of logarithms, entitled, "A most compendious and facile method for constructing the logarithms, and exemplified and demonstrated from the nature of numbers, without any regard to the hyperbola, with a speedy method for finding the number from the given logarithm."

Instead of the more ordinary definition of logarithms, viz, "numerorum proportionalium æquidifferentes comites," the learned author adopts this other, "numeri rationum exponentes," as better adapted to the principle on which logarithms are here constructed, considering them as the number of ratiunculae contained in the given ratios whose logarithms are in question. In this way he first arrives at the logarithmic series before given by Newton and others, and afterwards, by various combinations and sections of the ratios, he derives others, converging still faster than the former. Thus he found the logarithms of several ratios, as below, viz, when multiplied by the modulus peculiar to the scale of logarithms,

$$\begin{aligned} q &- \frac{1}{2}q^2 + \frac{1}{4}q^3 - \frac{1}{4}q^4 \&c, \text{ the log. of 1 to } 1+q, \\ q &+ \frac{1}{2}q^2 + \frac{1}{4}q^3 + \frac{1}{4}q^4 \&c, \text{ the log. of 1 to } 1-q, \\ \frac{x}{z} &- \frac{x^2}{2z^2} + \frac{x^3}{3z^3} - \frac{x^4}{4z^4} \&c, \text{ the log. of } a \text{ to } b, \text{ or} \\ \frac{x}{b} &+ \frac{x^2}{2b^2} + \frac{x^3}{3b^3} + \frac{x^4}{4b^4} \&c, \text{ the same log. of } a \text{ to } b, \text{ or} \\ \frac{2x^3}{z^2} &+ \frac{2x^5}{3z^5} + \frac{2x^7}{7z^7} \&c, \text{ the same log. of } a \text{ to } b, \\ \frac{x^2}{2z^3} &+ \frac{x^4}{4z^4} + \frac{x^6}{6z^6} + \frac{x^8}{8z^8} \&c, \text{ the log. of } \sqrt{ab} \text{ to } \frac{1}{2}z, \text{ or} \\ \frac{1}{y^2} &+ \frac{1}{3y^6} + \frac{1}{5y^{10}} + \frac{1}{7y^{14}} \&c, \text{ the same log. of } \sqrt{ab} \text{ to } \frac{1}{2}z. \end{aligned}$$

where a, b, q , are any quantities, and the values of x, y, z , are thus, viz, $x=b-a, z=b+a, y=ab+\frac{1}{2}z^2$.

Dr. Halley also, the first who performed the reverse of the problem, by assigning the number to a given logarithm; viz,

$$\frac{b}{a} = 1 + l + \frac{1}{2}l^2 + \frac{1}{2.3}l^3 + \frac{1}{2.3.4}l^4 \&c, \text{ or}$$

$$\frac{a}{b} = 1 - l + \frac{1}{2}l^2 - \frac{1}{2.3}l^3 + \frac{1}{2.3.4}l^4 \&c. \text{ where } l \text{ is the logarithm of the ratio of } a \text{ the less, to } b \text{ the greater of any two terms.}$$

Mr. Abraham Sharp of Yorkshire made many calculations and improvements in logarithms, &c. The most remarkable of these were, his quadrature of the circle to 72 places of figures, and his computation of logarithms to 61 figures, viz, for all numbers to 100, and for all prime numbers to 1100.

The celebrated Mr. Roger Cotes gave to the world a learned tract on the nature and construction of logarithms: this was first printed in the Philos. Trans. No. 338, and afterwards with his Harmonia Mensuraturum in 1722, under the title Logometria. This tract however has justly been complained of, as very obscure and intricate, and the principle is something between that of Kepler and the method of fluxions. He invented the terms modulus and modular ratio, this being the ratio

$$\text{of } 1 + \frac{1}{1} + \frac{1}{2} + \frac{1}{2.3} + \frac{1}{2.3.4} + \frac{1}{2.3.4.5} \&c \text{ to 1 or}$$

$$\text{of 1 to 1} - \frac{1}{1} + \frac{1}{2} - \frac{1}{2.3} + \frac{1}{2.3.4} - \frac{1}{2.3.4.5} \&c;$$

that is the ratio of 2718281828459 &c to 1,

or the ratio of 1 to 0.367879441171 &c;

the modulus of any system being the measure or logarithm of that ratio, which in the hyp. logarithms is 1, which in Briggs's or the common logarithms is 0·434294481903 &c.

The learned Dr. Brook Taylor gave another method of computing logarithms in the Philos. Trans. No. 352, which is founded on these three principles, viz, 1st, That the sum of the logarithms of any two numbers is the logarithm of the product of those numbers; 2d, That the logarithm of 1 is 0, and consequently that the nearer any number is to 1, the nearer will its logarithm be to 0; 3d, That the product of two numbers or factors, of which the one is greater, and the other less than 1, is nearer to 1, than that factor which is on the same side of 1 with itself; so of the two numbers $\frac{2}{3}$ and $\frac{1}{2}$, the product $\frac{1}{3}$ is less than 1, but yet nearer to it than $\frac{2}{3}$ is, which is also less than 1.—And on these principles he founds an ingenious, though not very obvious, approximation to the logarithms of given numbers.

In the Philos. Trans. a Mr. John Long gave a method of constructing logarithms, by means of a small table, something in the manner of one of Briggs's methods for the same purpose.

Also in the Philos. Trans. vol. 61, a tract on the construction of logarithms is given by the ingenious Mr. William Jones. In this method, all numbers are considered as some certain powers of a constant determined root; thus, any number x is considered as the z power of any root r , or $x = r^z$ is taken as a general expression for all numbers in terms of the constant root r and a variable exponent z . Now the index z being the logarithm of the number x , therefore to find this logarithm, is the same thing as to find what power of the radix r is equal to the number x .

An elegant tract on logarithms, as a comment on Dr. Halley's method, was also given by Mr. Jones in his Synopsis Palmariorum Mathesecorum, published in the year 1706.

In the year 1742, Mr. James Dodson published his Antilogarithmic Canon, containing all logarithms under 100,000, and their corresponding natural numbers to eleven places of figures, with all their differences and the proportional parts; the whole arranged in the order contrary to that used in the common tables of numbers and logarithms, the exact logarithms being here placed first, and their corresponding nearest numbers in the columns opposite to them.

And in 1767, Mr. Andrew Reid published an "Essay on Logarithms," in which he shows the computation of logarithms from principles depending on the binomial theorem, and on the nature of the exponents of powers, the logarithms of numbers being here considered as the exponents of the powers of 10. In this way he brings out the usual series for logarithms, and exemplifies Dr. Halley's construction of them. But for the particulars of this, and the methods given by the other authors, we must refer to the historical preface to my treatise on logarithms.

Besides the authors above-mentioned, many others have treated on the subject of logarithms; among the principal of whom are, Leibnitz, Euler, Maclaurin, Wolsius, Keill, Lagrange, and professor Simson in an ingenious geometrical tract on logarithms, contained in his posthumous works, elegantly printed at Glasgow in the year 1776, at the expense of the learned Earl Stanhope, and by his lordship disposed of in presents among gentlemen most eminent for mathematical learning.

For the description and uses of logarithms in numeral calculations, with the various methods of constructing

them, see the historical introduction to my Logarithms pa. 124 et seq.

Briggs's or Common LOGARITHMS, are those that have 1 for the logarithm of 10, or which have 0·434294481903 &c for the modulus; as has been explained above.

Hyperbolic LOGARITHMS, are those that were computed by the inventor Napier, and called also sometimes natural logarithms, having 1 for their modulus, or 2·302585092994 &c for the logarithm of 10. These have since been called hyperbolical logarithms, because they are analogous to the areas of right-angled hyperbola between the asymptotes and the curve. See LOGARITHMS, also HYPERBOLA and ASYMPTOTIC SPACE.

Logistic LOGARITHMS, are certain logarithms of sexagesimal numbers or fractions, useful in astronomical calculations. The logistic logarithm of any number of seconds, is the difference between the common logarithm of that number and the logarithm of 3600, the seconds in 1 degree.

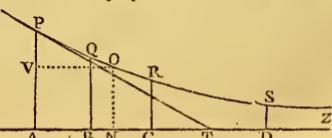

The chief use of the table of logistic logarithms, is for the ready computing a proportional part in minutes and seconds, when two terms of the proportion are minutes and seconds, or hours and minutes, or other such sexagesimal numbers. See the introd. to my Logarithms, pa. 144.

Imaginary LOGARITHM, a term used in the Log. of imaginary and negative quantities; such as $-a$, or $\sqrt{-a^2}$ or $a\sqrt{-1}$. The fluents of certain imaginary expressions are also imaginary logarithms; as of $\frac{x}{x\sqrt{-1}}$, or of $\frac{ax}{cx\sqrt{-1}}$, &c. See Euler Analys. Infin. vol. i. pa. 72, 74.

It is well known that the expression $\frac{x}{x}$ represents the fluxion of the logarithm of x , and therefore the fluent of $\frac{x}{x}$ is the logarithm of x ; and hence the fluent of $\frac{x}{x\sqrt{-1}}$ is the imaginary logarithm of x .

However, when these imaginary logarithms occur in the solutions of problems, they may be transformed into circular arcs or sectors; that is, the imaginary logarithm, or imaginary hyperbolic sector, becomes a real circular sector. See Bernoulli Oper. tom. i. pa. 400, and pa. 512. Maclaurin's Fluxions, art. 762. Cotes's Harmon. Mens. pa. 45. Walmesley, Anal. des Mes. pa. 63.

LOGARITHMIC, or LOGISTIC CURVE, a curve so called from its properties and uses, in explaining and constructing the logarithms, because its ordinates are in geometrical progression, while the abscissæ are in arithmetical progression; so that the abscissæ are as the logarithms of the corresponding ordinates. And hence the curve will be constructed in this manner: Upon any right line, as an axis, take the equal parts AB , BC , CD , &c, or the arithmetical progression AB , AC , AD , &c; and at the points A , B , C , D , &c, erect the perpendicular ordinates AP , BQ , CR , DS , &c, in a geometrical progression; so is the curve line drawn through all the points P , Q , R , S , &c, the logarithmic, or logistic curve; so called, because any abscissæ AB , is as the logarithm of its ordinate BQ . So that the axis ABC &c is an asymptote to the curve.

Hence, if any absciss $AN = x$, its ordinate $NO = y$, $AP = 1$, and $a =$ a certain constant quantity, or the modulus of the logarithms; then the equation of the curve is $x = a \times \log_e y = \log_e y^a$.

And if the fluxion of this equation be taken, it will be $\dot{x} = \frac{ay}{y}$; which gives this proportion,

$$\dot{y} : \dot{x} : : y : a$$

but in any curve $\dot{y} : \dot{x} : : y : a$: the subtangent AT ; therefore the subtangent of this curve is every-where equal to the constant quantity a , or the modulus of the logarithms.

To find the Area contained between two ordinates. Here the fluxion of the area A or yz is $y \times \frac{\dot{y}}{y} = \dot{y}$; and the correct fluent is $A = a \times (AP - y) = a \times (AP - NO) = a \times PV = AT \times PV$. That is, the area $APON$ between any two ordinates, is equal to the rectangle of the constant subtangent and the difference of the ordinates. And hence, when the absciss is infinitely long, or the farther ordinate equal to nothing, then the infinitely long area APZ is equal $AT \times AP$, or double the triangle APT .

To find the Solid formed by the curve revolved about its axis AZ . The fluxion of the solid is $s = py^2 \dot{x} =$

$py^2 \times \frac{\dot{y}}{y} = pay\dot{y}$, where p is $= 3.1416$; and the correct fluent is $s = \frac{1}{2}pa \times (AP^2 - y^2) = \frac{1}{2}p \times AT \times (AP^2 - NO^2)$, which is half the difference between two cylinders of the common altitude a or AT , and the radii of their bases AP , NO . And hence, supposing the solid infinitely long towards z , where y or the ordinate is nothing, the infinitely long solid will be equal to $\frac{1}{2}pa \times AP^2 = \frac{1}{2}p \times AT \times AT^2$, or half the cylinder on the same base and its altitude AT .

It has been said that Gunter gave the first idea of a curve whose abscisses are in arithmetical progression, while the corresponding ordinates are in geometrical progression, or whose abscisses are the logarithms of their ordinates; but I do not find it noticed in any part of his writings. This curve was afterwards considered by others, and named the logarithmic or logistic curve, by Huygens, in his *Dissertatio de Causa Gravitatis*, where he enumerates all the principal properties of it, showing its analogy to logarithms. Many other learned men have also treated of its properties; particularly Ja. Gregory, in the preface to his *Geometriae Pars Universalis* &c.; Le Seur and Jacquier, in their Comment on Newton's Principia; Dr. John Keill, in the elegant little Tract on Logarithms subjoined to his edition of Euclid's Elements; and Francis Maseres Esq. Cursitor Baron of the Exchequer, in his ingenious Treatise on Trigonometry: see also Bernoulli's Discourse in the Acta Eruditorum for the year 1696, pa. 216; Guido Grandi's Demonstratio Theorematum Huguenaeorum circa Logisticam seu Logarithmicam Lineam; and Emerson on Curve Lines, pa. 19.—It is indeed rather extraordinary that this curve was not sooner announced to the public, since it results immediately from Napier's manner of conceiving the generation of logarithms, by only supposing the lines which represent the natural numbers as placed at right angles to that upon which the logarithms are taken.

This curve greatly facilitates the conception of logarithms, and affords an almost intuitive proof of the very important property of their fluxions, or very small increments, namely, that the fluxion of the number is to the fluxion of the logarithm, as the number is to the subtangent; as also this property, that if three numbers be taken very nearly equal, so that their ratios may differ but a

little from a ratio of equality, as the three numbers 10000000, 10000001, 10000002, their differences will be very nearly proportional to the logarithms of the ratios of those numbers to each other: all which follows from the logarithmic arcs differing very little from their chords, when they are taken very small. And the constant subtangent of this curve is what was afterwards by Cotes called the modulus of the system of logarithms.

LOGARITHMIC, or LOGISTIC SPIRAL, is a curve constructed as follows. Divide the arch of a circle into any number of equal parts AB , BD , DE , &c; and upon the radii drawn to the points of division take cb , cd , ce , &c, in a geometrical progression; so is the curve $abde$ &c the logarithmic spiral; being thus called, because it is evident that AB , AD , AE , &c, being arithmetical, are as the logarithms of ca , cb , ed , ce , &c which are geometrical; and a spiral, because it winds continually about the centre c , coming continually nearer, but without ever really falling into it. In the Philos. Trans. Dr. Halley has happily applied this curve to the division of the meridian line in Mercator's chart. See also Cotes's *Harmonia Mens.*, Guido Grandi's *Demonstr. Theor. Huygen.*, the *Acta Erudit.* 1691, and Emerson's *Curves*, &c.

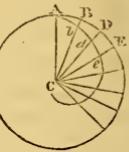

LOGISTICS, or LOGISTICAL ARITHMETIC, a name sometimes employed for the arithmetic of sexagesimal fractions, used in astronomical computations. This name was perhaps taken from a Greek treatise of Barlaemus, a monk, who wrote a book on Sexagesimal Multiplication, which he called logistic. Vossius places this author about the year 1350, but he mistakes the work for a treatise on algebra. The same term however has been used for the rules of computations in algebra, and in other species of arithmetic: witness the logistics of Vieta and other writers.

Shakerly, in his *Tabula Britannica*, has a table of logarithms adapted to sexagesimal fractions, which he calls logistical logarithms; and the expeditious arithmetic, obtained by means of them, he calls logistical arithmetic.

LOGISTICAL CURVE, LINE, or SPIRAL, the same as the Logistic; which see.

LONG (ROGER), D.D. master of Pembroke-hall in Cambridge, Lowndes's professor of astronomy in that university, &c. He was author of a well-known and much-approved treatise of astronomy, and the inventor of a remarkably curious astronomical machine. This was a hollow sphere, of 18 feet diameter, in which more than 30 persons might sit conveniently. Within side the surface, which represented the heavens, was painted the stars and constellations, with the zodiac, meridians, and axis parallel to the axis of the world, upon which it was easily turned round by a winch. He died, December 16, 1770, at 91 years of age.

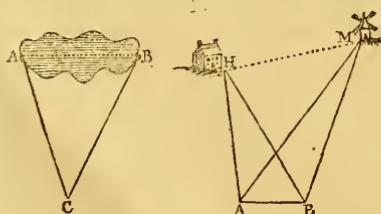

A few years before his death, Mr. Jones gave some anecdotes of Dr. Long, as follows: "He is now in the 88th year of his age, and for his years vegete and active. He was lately put in nomination for the office of vice-chancellor: he executed that trust once before, I think in the year 1737. He is a very ingenious person, and sometimes very facetious. At the public commencement, in the year 1713, Dr. Greene (master of Bennet-college, and afterwards bishop of Ely) being then vice-chancellor, Mr. Long was pitched upon for the tripos performance; it was

witty and humourous, and has passed through divers editions. Some that remembered the delivery of it, told me, that in addressing the vice-chancellor (whom the university wags usually styled Miss Greene), the tripos-orator, being a native of Norfolk, and assuming the Norfolk dialect, instead of saying Domine Vice-Cancellarie, archly pronounced the words thus, Domina Vice-Cancellaria; which occasioned a general smile in that great auditory. His friend the late Mr. Bonfoy of Ripton related to me the following little incident: 'That he and Dr. Long walking together in Cambridge in a dusky evening, and coming to a short post fixed in the pavement, which Mr. Bonfoy in the midst of chat and inattention took to be a boy standing in his way, he said in a hurry, "Get out of my way, boy!" "That boy, Sir," said the doctor very calmly and slyly, "is a post-boy, who turns out of his way for nobody." I could recollect several other ingenious repartees if there were occasion. One thing is remarkable, he never was a hale and hearty man, always of a tender and delicate constitution, yet took great care of it: his common drink water; he always dines with the fellows in the hall. Of late years he left off eating flesh; in the room thereof, puddings, vegetables, &c; sometimes a glass or two of wine."

LONGIMETRY, the art of measuring lengths or distances, both accessible and inaccessible, forming a part of what is called heights and distances, being an application of geometry and trigonometry to such measurements. As to accessible lengths, they are easily measured by the actual application of a rod, a chain, or wheel, or some other measure of length.

But inaccessible lengths require the practice and properties of geometry and trigonometry, either in the measurement and construction, or in the computation. For example, Suppose it were required to know the length or distance between the two places A and B, to which places there is free access, but not to the intermediate parts, on account of water or some other impediment; measure therefore, from A and B, the distances to any convenient place C, which suppose to be thus, viz. AC = 735, and BC = 840 links; and let the angle at C, taken with a theodolite or other instrument, be $55^{\circ} 40'$. From these measures the length or distance AB may be determined, either by geometrical construction, or by trigonometrical computation. Thus, first lay down an angle C = $55^{\circ} 40'$, and upon its legs set off, from any convenient scale of equal parts, CA = 735, and CB = 840; then measure the distance between the points A and B by the same scale of equal parts, which will be found to be 740 nearly. Or

thus by calculation,

$$840 \cdot 1575 - 55^{\circ} 40' = 124^{\circ} 20', \text{ its half } 62^{\circ} 10',$$

735

$$\begin{array}{rccccc} \text{Sum} & 1575 & - & - & - & 1.1972806 \\ \text{Dif.} & 105 & - & - & - & 0.0211893 \end{array}$$

Tang.	$62^{\circ} 10'$	-	-	-	10 277 3793
Tang.	7	$11\frac{1}{4}$	-	-	9 101 2880
s.	Sum or $\angle \alpha$	$= 99^{\circ} 21\frac{1}{4}$	-	-	9 971 1092
to s.	$\angle c$	$= 55^{\circ} 40'$	-	-	9 916 8593
So BC	$= 840$	-	-	-	0 924 2793
To AB	$= 741\cdot 2$	-	-	-	0 869 9404

For a 2d Example—Suppose it were required to find the distance between two inaccessible objects, as between the house and mill, H and M; first measure any convenient line on the ground, as AB, 300 yards; then at the station A take the angles $BAM = 58^{\circ} 20'$, and $MAH = 53^{\circ}$; also at the station B take the angles $ABH = 53^{\circ} 30'$, and $HBM = 45^{\circ} 15'$; hence the distance or length HM may be found, either by geometrical construction, or by trigonometrical calculation, thus :

First draw a line AB of the given length of 300, by a convenient scale of equal parts; then at the point A lay down the angles BAM and MAH of the magnitudes above given; and also at the point B the given angles ABH and HBM ; then by applying the length HM to the same scale of equal parts, it is found to be nearly 480 yards.

Otherwise, by calculation. First, by adding and subtracting the angles, there is found as below :

	$37^{\circ} 00'$	$58^{\circ} 20'$	$53^{\circ} 30'$
58	20	53	30
	53	30	45
sums	148	50	157
from	180	00	00
$\angle AHB$	31	10	22
		55	$\angle AMB$

Then, as $\sin. AHB : \sin. ABH :: AB : AH = 465\cdot 9776$, and, as $\sin. AMB : \sin. ABM :: AB : AM = 761\cdot 4655$,

their sum is $1227\cdot 4431$ and their diff. $295\cdot 4879$

Then as $\text{sum } AM + AH : \text{dif. } AM - AH ::$

$$\text{tang. } \frac{1}{2} \text{AHM} + \frac{1}{2} \text{AMH} = 71^{\circ} 30',$$

$$\text{to tang. } \frac{1}{2} \text{AHM} - \frac{1}{2} \text{AMH} = 35^{\circ} 44'$$

the dif. of which is $AMH = 35^{\circ} 46'$.

Lastly, as $s. AMH : s. MAH :: AH : HM = 479\cdot 7933$, the distance sought.

LONGITUDE of the Earth, is sometimes used to denote its extent from west to east, according to the direction of the equator: by which it stands contradistinguished from the latitude of the earth, which denotes its extent from one pole to the other.

LONGITUDE of a Place, in Geography, is its longitudinal distance from some first meridian, which is assumed arbitrarily by different nations: the English call the first meridian, that which passes over the Royal Observatory at Greenwich; the French take the meridian of Paris for the first meridian; the Spaniards, Madrid; and so most other nations reckon that the first meridian which passes over their metropolis.

The longitude of any place is therefore an arch of the equator intercepted between the meridian of that place, and the first meridian.

LONGITUDE in the Heavens, as of a star, &c, is an arch of the ecliptic, counted from the beginning of Aries, to the place where it is cut by a circle perpendicular to it, and passing through the place of the star.

LONGITUDE of the Sun or Star from the next equinoctial point, is the degrees they are distant from the beginning of Aries or Libra, either before or after them; which can never exceed 180 degrees.

Longitude, Geocentric, Heliocentric, &c. the longitude of a planet as seen from the earth, or from the sun. See the respective terms.

Longitude, in Navigation, is the distance of a ship, or place, east or west, from some other place or meridian, counted in degrees of the equator. When this distance is counted in leagues, or miles, or in degrees of the meridian, and not in those proper to the parallel of latitude, it is usually called departure.

An easy practicable method of finding the longitude at sea, is the only thing wanted to render the art of navigation perfect, and is a problem that has greatly perplexed mathematicians for the last two centuries: accordingly most of the commercial nations of Europe have offered great rewards for the discovery of it; and in consequence very considerable advances have been made towards a perfect solution of the problem, especially by the English.

In the year 1598, the government of Spain offered a reward of 1000 crowns for the solution of this problem; and soon after the States of Holland offered 10 thousand florins for the same. Encouraged by such offers, in 1635, M. John Morin, professor of mathematics at Paris, proposed to cardinal Richelieu, a method of resolving it; and though the commissioners, who were appointed to examine this method, on account of the imperfect state of the lunar tables, judged it insufficient, cardinal Mazarin, in 1645, procured for the author a pension of 2000 livres.

In 1714 an act was passed in the British parliament, allowing 2000*l.* towards making experiments; and also offering a reward to the person who should discover the longitude at sea, proportioned to the degree of accuracy that might be attained by such discovery: viz, a reward of 10,000*l.* if it determines the longitude to one degree of a great circle, or 60 geographical miles; 15,000*l.* if it determines the same to two-thirds of that distance; and 20,000*l.* if it determines it to half that distance; with other regulations and encouragements. 12 Ann. cap. 15. See also stat. 14 Geo. 2, cap. 39, and 26 Geo. 2, cap. 25. But, by stat. Geo. 3, all former acts concerning the longitude at sea are repealed, except so much of them as relates to the appointment and authority of the commissioners, and such clauses as relate to the publishing of nautical almanacs, and other useful tables; and it enacts, that any person who shall discover a method for finding the longitude by means of a time-keeper, the principles of which not having hitherto been made public, shall be entitled to the reward of 5000*l.* if it shall enable a ship to keep her longitude, during a voyage of 6 months, within 60 geographical miles, or one degree of a great circle; to 7500*l.* if within 40 geographical miles, or two-thirds of a degree of a great circle; or to a reward of 10,000*l.* if within 30 geographical miles, or half a degree of a great circle. But if the method shall be by means of improved solar and lunar tables, the author of them shall be entitled to a reward of 5000*l.* if they show the distance of the moon from the sun and stars within 15" of a degree, answering to about 7' of longitude, after making an allowance of half a degree for the errors of observation, and after comparison with astronomical observations for a period of 18½ years, or during the period of the irregularities of the lunar motions. Or that in case any other method shall be proposed for finding the longitude at sea, besides those before-mentioned, the author shall be entitled to 5000*l.* if it shall determine the longitude within one degree of a great circle, or 60 geographical miles; to 7500*l.* if

within two-thirds of that distance; and to 10,000*l.* if within half the said distance.

Accordingly, many attempts have been made for such discovery, and several ways proposed, with various degrees of success. These however have been chiefly directed to methods of determining the difference of time between any two points on the earth; for the longitude of any place being an arc of the equator intercepted between two meridians, and this arc being proportional to the time required by the sun to move from the one meridian to the other, at the rate of 4 minutes of time to one degree of the arc, it follows that the difference of time being known, and turned into degrees according to that proportion, it will give the longitude.

This measurement of time has been attempted by some persons by means of clocks, watches, and other automata: for if a clock or watch were contrived to go uniformly at all seasons, and in all places and situations; such a machine being regulated, for instance, to London or Greenwich time, would always show the time of the day at London or Greenwich, wherever it should be carried to; then the time of the day at this place being found by observations, the difference between these two times would give the difference of longitude, according to the proportion of one degree to 4 minutes of time.

Gemma Frisius, in his tract *De Principiis Astronomiae et Geographiae*, printed at Antwerp in 1530, it seems, first suggested the method of finding the longitude at sea by means of watches, or time-keepers; which machines, he says, were then but lately invented. And soon after, the same was attempted by Mctius, and some others; but the state of watch-making was then too imperfect for that purpose. Dr. Hooke and Mr. Huygens also, about the year 1664, applied the invention of the pendulum-spring to watches; and employed it for the purpose of discovering the longitude at sea. Some disputes however between Dr. Hooke and the English ministry prevented any experiments from being made with watches constructed by him; but many experiments were made with some constructed by Huygens; particularly Major Holmes, in a voyage from the coast of Guinea in 1665, by one of these watches predicted the longitude of the island of Fuego to a great degree of accuracy. This success encouraged Huygens to improve the structure of his watches, (see Philos. Trans. for May 1669); but experience soon convinced him, that unless methods could be discovered for preserving the regular motion of such machines, and preventing the effects of heat and cold, and other disturbing causes, they could never answer the intention of discovering the longitude, and on this account his attempts failed.

The first person who turned his thoughts this way, after the public encouragement held out by the act of 1714, was Henry Sully, an Englishman; who, in the same year, printed at Vienna, a small tract on the subject of watch-making; and afterwards removing to Paris, he employed himself there in improving time-keepers for the discovery of the longitude. It is said he greatly diminished the friction in the machine, and rendered uniform that which remained: and to him is principally to be attributed what is yet known of watch-making in France: for the celebrated Julier le Roy was his pupil, and to him owed most of his inventions, which he afterwards perfected and executed: and this gentleman, with his son, and M. Berthoud, are the principal persons in France who have

turned their thoughts this way since the time of Sully. Several watches made by these last two artists, have been tried at sea, it is said with good success, and many accounts have been published of these trials, at considerable length.

In the year 1726 our countryman, Mr. John Harrison, produced a time-keeper of his own construction, which did not err above one second in a month, for 10 years together: and in the year 1736 he had a machine tried in a voyage to and from Lisbon; which was the means of correcting an error of almost a degree and a half in the computation of the ship's reckoning. In consequence of this success, Mr. Harrison received public encouragement to proceed, and he made three other time-keepers, each more accurate than the former, which were finished successively in the years 1739, 1758, and 1761; the last of which proved so much to his own satisfaction, that he applied to the commissioners of longitude to have this instrument tried in a voyage to some port in the West-Indies, according to the directions of the statute of the 12th of Anne above cited. Accordingly, Mr. William Harrison, son of the inventor, embarked in November 1761, on a voyage for Jamaica, with this 4th time-keeper or watch; and on his arrival there, the longitude, as shown by the time-keeper, differed but one geographical mile and a quarter from the true longitude, deduced from astronomical observations. The same gentleman returned to England, with the time-keeper, in March 1762; when he found that it had erred, in the 4 months, no more than $1' 54'' \frac{1}{2}$ in time, or $28\frac{1}{2}$ minutes of longitude; whereas the act requires no greater exactness than 30 geographical miles, or minutes of a great circle, in such a voyage. Mr. Harrison now claimed the whole reward of 20,000*l.*, offered by the said act: but some doubts arising in the minds of the commissioners, concerning the true situation of the island of Jamaica, and the manner in which the time at that place had been found, as well as at Portsmouth; and it being farther suggested by some, that though the time-keeper happened to be right at Jamaica, and after its return to England, it was by no means a proof that it had been always so in the intermediate times; another trial was therefore proposed, in a voyage to the island of Barbadoes, in which precautions were taken to obviate as many of these objections as possible. Accordingly, the commissioners previously sent out proper persons to make astronomical observations at that island, which, when compared with other corresponding ones made in England, would determine, beyond a doubt, its true situation: and Mr. William Harrison again set out with his father's time-keeper, in March 1764, the watch having been compared with equal altitudes at Portsmouth, before he set out, and he arrived at Barbadoes about the middle of May; where, on comparing it again by equal altitudes of the sun, it was found to show the difference of longitude, between Portsmouth and Barbadoes, to be $3^{\circ} 55' 3''$; the true difference of longitude between these places, by astronomical observations, being $3^{\circ} 54' 20''$; so that the error of the watch was $43''$, or $10' 45''$ of longitude. In consequence of this, and the former trials, Mr. Harrison received one moiety of the reward offered by the 12th of Queen Anne, after explaining the principles on which his watch was constructed, and delivering this as well as the three former to the commissioners of the longitude, for the use of the public: and he was promised the other moiety of the reward, when other time-keepers should be made, on the

same principles, either by himself or others, performing equally well with that which he had last made. In the mean time, this last time-keeper was sent down to the Royal Observatory at Greenwich, to be tried there under the direction of the Rev. Dr. Maskelyne, the astronomer-royal. But it did not appear, during this trial, that the watch went with the regularity that was expected; from which it was apprehended, that the performance even of the same watch, was not at all times equal; and consequently that little certainty could be expected in the performance of different ones. Moreover, the watch was now found to go faster than during the voyage to and from Barbadoes, by 18 or 19 seconds in 24 hours: but this circumstance was accounted for by Mr. Harrison; who informs us that he had altered the rate of its going by trying some experiments, which he had not time to finish before he was ordered to deliver up the watch to the Board. Soon after this trial, the commissioners of longitude agreed with Mr. Kendal, one of the watch-makers appointed by them to receive Mr. Harrison's discoveries, to make another watch on the same construction with this, to determine whether such watches could be made from the account which Mr. Harrison had given, by other persons, as well as himself. The event proved the affirmative; for the watch produced by Mr. Kendal, in consequence of this agreement, went considerably better than Mr. Harrison's did. Mr. Kendal's watch was sent out with Capt. Cook, in his 2d voyage towards the south pole and round the globe, in the years 1772, 1773, 1774, and 1775; when the only fault found in the watch was, that its rate of going was continually accelerated; though in this trial, of 3 years and a half, it never amounted to $14'' \frac{1}{2}$ a day. The consequence was, that the house of commons in 1774, to whom an appeal had been made, were pleased to order the 2d moiety of the reward to be given to Mr. Harrison, and to pass the act above-mentioned. Mr. Harrison had also at different times received some other sums of money, as encouragements to him to continue his endeavours, from the Board of Longitude, and from the India Company, as well as from many individuals. Mr. Arnold, Mr. Mudge, Mr. Ernshaw, Mr. Hardy, and some other persons have since also made several very good watches for the same purpose.

Others have proposed various astronomical methods for finding the longitude, which chiefly depend on having an ephemeris or almanac suited to the meridian of some place, as Greenwich for instance, to which the nautical almanac is adapted, that shall contain for every day computations of the times of all remarkable celestial motions and appearances, as adapted to that meridian. So that, if the hour and minute be known when any of the same phenomena are observed in any other place, whose longitude is desired, the difference between this time and that to which the time of the said phenomenon was calculated and set down in the almanac, will be known, and consequently the difference of longitude also becomes known, between that place and Greenwich, allowing at the rate of 15 degrees to an hour.

Now it is easy to find the time at any place, by means of the altitude or azimuth of the sun or stars; which time it is necessary to find by the same means, both in these astronomical modes of determining the longitude, and in the former by a time-keeper; and it is the difference between that time, so determined, and the time at Greenwich, known either by the time-keeper or by the astrono-

mical observations of celestial phenomena, which gives the difference of longitude, at the rate above-mentioned. But here the great difficulty is, that there are only a few phenomena proper, or capable of being thus observed; for all slow motions, such as belong to the planet Saturn for instance, are quite excluded, as affording too small a difference, in a considerable space of time, to be properly observed; indeed there are no phenomena in the heavens proper for this purpose, except the eclipses or motions of Jupiter's satellites, and the eclipses or motions of the moon, viz, such as her distance from the sun or certain fixed stars lying near her path, or her longitude or place in the zodiac, &c.

1st, That by the eclipses of the moon is very easy, and sufficiently accurate, if they did but happen often, as every night. For at the moment when the beginning, or middle, or end of an eclipse is observed by a telescope, there is no more to be done but to determine the time by observing the altitude or azimuth of some known star; which time being compared with that in the tables, set down for the happening of the same phenomenon at Greenwich, gives the difference in time, and consequently of longitude sought. But as the beginning or end of an eclipse of the moon cannot generally be observed nearer than one minute, and sometimes 2 or 3 minutes of time, the longitude cannot certainly be determined by this method, from a single observation, nearer than one degree of longitude. However, by two or more observations, as of the beginning and end &c, a much greater degree of exactness may be attained.

2d, The moon's place in the zodiac is a phenomenon more frequent than that of her eclipses; but then the observation of it is difficult, and the calculus perplexed and intricate, by reason of two parallaxes; so that it is hardly practicable, to any tolerable degree of accuracy.

3d, But the moon's distances from the sun, or certain fixed stars, are phenomena to be observed many times in almost every night, and afford a good practical method of determining the longitude of a ship at almost any time; either by computing, from thence, the moon's true place, to compare with the same in the almanac; or by comparing her observed distance itself with the same as there set down.

It is said that the first person who recommended the finding the longitude from this observed distance between the moon and some star, was John Werner, of Nuremberg, who printed his annotations on the first book of Ptolemy's Geography in 1514. And the same thing was recommended in 1524, by Peter Apian, professor of mathematics at Ingolstadt; also about 1530, by Oronce Finé, of Briangon; and the same year by the celebrated Kepler, and by Gemma Frisius, at Antwerp; and in 1560, by Nonius or Pedro Nunez.

Nor were the English mathematicians behind hand on this head. In 1665 Sir Jonas Moore prevailed on king Charles the 2d to erect the Royal Observatory at Greenwich, and to appoint Mr. Flamsteed his astronomical observer, with this express command, that he should apply himself with the utmost care and diligence to the rectifying the table of the motions of the heavens, and the places of the fixed stars, in order to find out the longitude at sea, for perfecting the art of navigation. And to the fidelity and industry with which Mr. Flamsteed executed his commission, it is that we are chiefly indebted for that curious theory of the moon, which was afterwards formed by

the immortal Newton. This incomparable philosopher made the best possible use of the observations with which he was furnished; but as these were interrupted and imperfect, his theory would sometimes differ from the heavens by 5 minutes or more.

Dr. Halley bestowed much time on the same object; and a starry zodiac was published under his direction, containing all the stars to which the moon's appulse can be observed; but for want of correct tables, and proper instruments, he could not proceed in making the necessary observations. In a paper on this subject, in the Philos. Trans. No. 421, he expresses his hope, that the instrument just invented by Mr. Hadley might be applied to taking angles at sea with the desired accuracy. This great astronomer, and after him Lacaille, and others, have reckoned the best astronomical method for finding the longitude at sea, to be that in which the distance of the moon from the sun or from a star is used; for the moon's daily motion being about 13 degrees, her hourly mean motion is above half a degree, or one minute of a degree in two minutes of time; so that an error of one minute of a degree in position will produce an error of 2 minutes in time, or half a degree in longitude. Now from the great improvements made by Newton in the theory of the moon, and more lately by Euler and others on his principles, Professor Mayer of Gottingen, was enabled to calculate lunar tables more correct than any former ones; having so far succeeded as to give the moon's place within one minute of the truth, which has been proved by a comparison of the tables with the observations made at the Greenwich observatory by the late Dr. Bradley, and by Dr. Maskelyne, the astronomer royal; and the same have been still further improved under his direction, by the late Mr. Charles Mason, by several new equations, and the whole computed to tenths of a second. These new tables, when compared with the above-mentioned series of observations, a proper allowance being made for the unavoidable error of observation, seem to give always the moon's longitude in the heavens correctly within 30 seconds of a degree; which greatest error, added to a possible error of one minute in taking the moon's distance from the sun or a star at sea, will at a medium only produce an error of 42 minutes of longitude. Further successive improvements in them have since been made, by the labours of Messieurs Lagrange, Laplace, Lalande, Delambre, Burg, and Vince; by which means it is thought the astronomical tables have been brought to the most correct form that the present state of astronomical knowledge will permit.

To facilitate the use of the tables, Dr. Maskelyne proposed a nautical ephemeris, the scheme of which was adopted by the commissioners of longitude, and first executed in the year 1767; since which time it has been regularly continued, and published as far as for the year 1816. But as the rules that were given in the appendix to one of those publications, for correcting the effects of refraction and parallax, were thought too difficult for general use, they have been reduced to tables. So that, by the help of the ephemeris, these tables, and others that are also provided by the Board of Longitude, the calculations relating to the longitude, which could not be performed by the most expert mathematician in less than 4 hours, may now be completed with great ease and accuracy in half an hour.

As this method of determining the longitude depends on the use of the tables annually published for this purpose,

those who wish for further information, are referred to the instructions that accompany them, and particularly to those that are annexed to the Tables requisite to be used with the Astronomical and Nautical Ephemeris, 3d edit. 1802. See LUNAR Method, below.

4th, The phenomena of Jupiter's satellites have commonly been preferred to those of the moon, for finding the longitude; because they are less liable to parallaxes than these are, and besides they afford a very commodious observation whenever the planet is above the horizon. Their motion is very swift, and must be calculated for every hour. These satellites of Jupiter were no sooner announced by Galileo, in his Syderius Nuncius, first printed at Venice in 1610, than the frequency of their eclipses recommended them for this purpose; and among those who treated on this subject, none was more successful than Cassini. This great astronomer published, at Bologna, in 1688, tables for calculating the appearances of their eclipses; with directions for finding the longitudes of places by them; and being invited to France by Louis the 14th, he there, in the year 1693, published more correct tables of the same. But the mutual attractions of the satellites rendering their motions very irregular, those tables soon became useless for this purpose; insomuch that they require to be renewed from time to time; a service which has been performed by several ingenious astronomers, as Dr. Pound, Dr. Bradley, M. Cassini the son, and more especially by Mr. Wargentin, whose tables are much esteemed, and have been published in several places, as well as in the Nautical Almanacs for 1771 and 1779.

Now, to find the longitude by these satellites; with a good telescope observe some of their phenomena, as the conjunction of two of them, or of one of them with Jupiter, &c.; and at the same time find the hour and minute, from the altitudes of the stars, or by means of a clock or watch, previously regulated for the place of observation; then, consulting tables of the satellites, observe the time when the same appearance happens in the meridian of the place for which the tables are calculated; and the difference of time, as before, will give the longitude.

The eclipses of the first and second of Jupiter's satellites are the most proper for this purpose; and as they happen almost daily, they afford a ready means of determining the longitude of places at land, having indeed contributed much to the modern improvements in geography; and if it were possible to observe them with proper telescopes, in a ship under sail, they would be of great service in ascertaining its longitude from time to time. To obviate the inconvenience to which these observations are liable from the motions of the ship, a Mr. Irwin invented what he called a marine chair; this was tried by Dr. Maskelyne, in his voyage to Barbadoes, when it was not found that any benefit could be derived from the use of it. And indeed, considering the great power requisite in a telescope proper for these observations, and the violence, as well as irregularities in the motion of a ship, it is to be feared that the complete management of a telescope on ship-board, will always remain among the desiderata in this part of nautical science. And further, since all methods that depend on the phenomena of the heavens, have also this other defect, that they cannot be observed at all times, this renders the improvement of time-keepers an object of the more importance.

Many other schemes and proposals have been made by different persons, but most of them of very little or no

use; such as by the space between the flash and report of a great gun, proposed by Messrs. Whiston and Ditton; and another proposed by Mr. Whiston, by means of the inclinatory or dipping needle; besides a method by the variation of the magnetic-needle, &c., &c.

For approximate constructions for clearing the lunar distances from the effects of parallax and refraction, the reader may consult Dr. Kelly's Spherics and Nautical Astronomy, &c. And for more detailed information respecting the above, and other methods of ascertaining the longitude, see Dr. Mackay's and Mr. Mendoza's valuable works; also Vince's Astronomy, vol. 2, pa. 515, &c., and O. Gregory's Astronomy, pa. 446 to 470.

LONGITUDE OF MOTION, is a term used by Dr. Wallis for the measure of motion, estimated according to its line of direction; or it is the distance or length gone through by the centre of any moving body, as it moves on in a right line.—The same author calls the measure of any motion, estimated according to the line of direction of the vis motrix, the altitude of it.

LONGOMONTANUS (CHRISTIAN), a learned astronomer, born in Denmark in 1562, in the village of Longomontum, whence he took his name. Vossius, by mistake, calls him Christopher. He was the son of a poor ploughman, and he was obliged to suffer, during his studies, all the hardships to which he could be exposed, dividing his time, like the philosopher Cleanthes, between the cultivation of the earth and the lessons he received from the minister of the place. At length, at 15 years of age he stole away from his family, and went to Wiburg, where there was a college, in which he spent 11 years; and though he was obliged to earn his livelihood as he could, his close application to study, enabled him to make a great progress in learning, particularly in the mathematical sciences.

Hence he went to Copenhagen; where the professors of that university soon conceived a very high opinion of him, and recommended him to the celebrated Tycho Brahé, with whom Longomontanus lived 8 years, and was of great service to him in his observations and calculations. At length, being very desirous of obtaining a professor's chair in Denmark, Tycho Brahé consented, with some difficulty, to his leaving him, giving him a discharge filled with the highest testimonies of his esteem, and furnishing him with money for the expense of his long journey from Germany, whither Tycho had retired. He accordingly obtained a professorship of mathematics in the university of Copenhagen in 1605, the duty of which he discharged very worthily till his death, which happened in 1647, at 85 years of age.

Longomontanus was author of several works, which show great talents in mathematics and astronomy. The most distinguished of which, is his Astronomica Danica, first printed in 4to, 1621, and afterwards in folio in 1640, with augmentations. He amused himself with endeavouring to square the circle, and pretended that he had made the discovery of it; but our countryman Dr. John Pell attacked him warmly on that subject, and proved that he was mistaken.—It is remarkable, that obscure as his village and father were, he contrived to dignify and eternalize them both; for he took his name from his village, and in the title page to some of his works he wrote himself Christianus Longomontanus Severini filius, his father's name being Severin or Severinus.

LOXODROMIC CURVE, or SPIRAL, is the same as the rhumb line, or path of a ship sailing always on the same

course in an oblique direction, or making always the same angle with every meridian. It is a species of logarithmic spiral, described on the surface of the sphere, having the meridians for its radii.

LOXODROMICS, the art or method of oblique sailing, by the loxodromic or rhumb line.

LOZENGE, an oblique-angled parallelogram; being otherwise called a rhombus, or a rhomboide.

LUBIENIETSKI (STANISLAUS), a Polish gentleman, born at Cracow, in 1623, and educated with great care by his father. He was learned in astronomy, and became a celebrated Socinian minister. He took great pains to obtain a toleration from the German princes for his Socinian brethren. His endeavours however were all in vain; being himself persecuted by the Lutheran ministers, and banished from place to place; till at length he was banished out of the world, with his two daughters, by poison, in 1675, his wife narrowly escaping.

We have, of his writing, A History of the Reformation in Poland; and a Treatise on Comets, entitled Theatrum Cometum, printed at Amsterdam in 2 volumes folio; which is a most elaborate work, containing a minute historical account of every single comet that had been seen or recorded.

LUCIDA CORONÆ, a fixed star of the 2d magnitude, in the northern crown. See CORONA Borealis.

LUCIDA HYDRÆ. See COR Hydra.

LUCIDA LYRÆ, a bright star of the first magnitude in the constellation Lyra.

LUCIFER, a name given to the planet Venus, when she appears in the morning before sunrise.

LUDOLPH VAN CEULEN. See CEULEN.

LUMINARIES, a term used for the sun and moon, by way of eminence, for their extraordinary lustre, and the great quantity of light they give us.

LUNA, the Moon; which see.

LUNAR, something relating to the moon.

LUNAR Cycle, or Cycle of the Moon. See CYCLE.

LUNAR Distance, in nautical astronomy, a term denoting the distance of the moon from the sun, or from a fixed star lying nearly in the line of its path. The measurement of the apparent lunar distances, and the determination of the true lunar distances from thence, are of great use in determining the longitude at sea, or on land.

LUNAR Method for the Longitude, a method of keeping or finding the longitude by means of the moon's motions, particularly by her observed distances from the sun and stars; for which, see the article LONGITUDE.

This method consists in taking and reducing the distance between the moon and the sun or a fixed star, in order to find the longitude at sea; which has been already explained generally under the article LONGITUDE; but the great utility and importance of the subject require here a further and more minute explanation of its principles and operations, with an account of the different methods that have been devised for obtaining the solution; and I shall conclude the article with a very simple projection, invented by Dr. Kelly, which is found sufficiently correct for the common purposes of nautical practice, and even where the greatest accuracy is required, it is found useful as a guide or check to calculation.

The lunar method of finding the longitude at sea, is the greatest modern improvement in navigation. In order to form a clear and comprehensive idea of the subject, it should be first considered, that in the most practical methods

of finding the longitude at sea by celestial observations, the moon is the chief instrument; for the quickness of her motion renders her peculiarly well adapted for measuring small portions of correspondent time.—Now, as she is seen in the same part of the heavens nearly, at the same instant of absolute time, from all parts of the earth where she is visible, and as she is continually and sensibly changing her place, it is evident that if two correspondent observers were to note the precise moment of their respective times, when she is seen in any particular part of the heavens the difference between those times would show the difference of longitude.

In every method of finding the longitude by the moon, the first object is to be able to ascertain the part of the heavens where she is:—this is easily seen at the time of her eclipses, or at the occultation of a fixed star, and these were naturally the first methods resorted to; but they occur too seldom for general use: the moon's place however may be marked with equal precision, by taking her distance from some fixed object, whose latitude and longitude are known; the stars in or near the zodiac are preferred, as the nearer such objects are to the moon's path, the quicker will be her motion with respect to them: and though her motion is not uniform, yet, during the short space of time that she is near any star, it may be considered as such.

It may be observed, that if two persons under different meridians were to mark the moon's place, and also their relative times of observation, they might thence tell their difference of longitude; but they could not communicate their observations sufficiently soon for practical purposes; but even admitting the possibility of this, it were necessary that the longitude of one place should be known, in order to determine that of the other. Now the Nautical Almanac is calculated to supply all these wants. This work may be considered a perpetual observer, that communicates universally and instantaneously certain celestial appearances, as they take place at Greenwich observatory. Here the distances are given between the moon and the sun, and certain remarkable stars in or near the zodiac, for every three hours; and any intermediate distance, or time, may be thence found by the rule of proportion, with sufficient accuracy. If therefore, under any meridian, a lunar distance be observed, the difference between the time of observation and the time in the almanac, when the same distance was to take place at Greenwich, will show the longitude. For example, if the observed distance between the sun and moon be 50° at 8 o'clock, but by the almanac the same distance of 50° will take place at Greenwich at 6, it is evident that the difference between the observed and computed time is 2 hours, and therefore the longitude is 30° ; and it is also clear that the longitude is east, the time being most advanced at the place of observation.

A method so apparently simple must have been long since adopted, but for two difficulties which occurred: one the want of proper instruments; which now has been happily supplied by the invention and subsequent improvement of Hadley's quadrant; and the other, correct lunar tables; for the moon, though so near and so conspicuous to the earth, has always perplexed astronomers more than any other celestial body. The various inequalities of her motions were never properly understood, until Sir Isaac Newton discovered the physical laws which govern them; and from his theory professor Mayer formed

lunar tables, from which those tables, in the Nautical Almanac, of the lunar distances were calculated, under the direction of Dr. Maskelyne for many years. In 1806 the French Board of Longitude published new Lunar Tables, calculated by Du Burg, from the theory of Laplace and the observations of Dr. Maskelyne; and from these tables the lunar distances in the Nautical Almanac of 1813, and the following years, are computed.

The above two difficulties having been obviated, a third seems still to remain; and though this is in some measure removed by the application of the Nautical Almanac and requisite tables, yet still the calculation is more tedious than might be wished; nor is it possible to render it much shorter, as the problem necessarily comprehends the solutions of two spheric triangles: this arises from the circumstance of the observed distances between the heavenly bodies not being the true distances; for the altitudes of those bodies are more or less affected both by refraction and parallax; and though these effects only operate in a vertical direction, yet that which changes the altitude of two bodies, must also change the distance between them. This is evident from the consideration, that the altitude of a celestial object is an arc of an azimuth circle intercepted between the object and the horizon, and as all azimuth circles incline gradually to each other, from the horizon to the zenith, where they meet, it is plain that the more two bodies are apparently raised, the less will be their apparent distance asunder, and the contrary.

It has been already stated that the heavenly bodies are raised by refraction, and depressed by parallax; and that these effects are greatest in the horizon, and gradually diminish to the zenith, where they become nothing. Refraction depends on altitude alone, but parallax depends on both altitude and distance from the earth. All celestial objects, except the moon, are more affected by refraction than by parallax, and therefore appear above their true places; but the moon is always seen, excepting in the zenith, below her true place, being more affected by parallax than by refraction, on account of her proximity to the earth.

These effects of parallax and refraction, though counteracting each other, seldom do it so equally as to render all correction unnecessary. Sometimes the apparent distance is nearly a whole degree more or less than the true distance; and the principal cause of so great a difference is the moon's parallax; for this body, which is the chief guide to the longitude, is also the great cause of error in the distances, and is therefore the principal object of correction.

In making a lunar observation, four persons are usually employed, one of whom takes the distance, two the altitudes, and the fourth notes the time. These things should be performed at the same instant; and if the observation be repeated several times, and a mean taken, the work is likely to be the more correct; and great care is here necessary, for an error in this part of the operation, particularly in taking the distance, will pervade the subsequent parts of the work, and will of course produce a wrong solution. The manner of adjusting the instruments, and of making the observations, is best taught by practice. Those who wish for written instructions on the subject, are referred to the British Mariner's Guide by Dr. Maskelyne, to Dr. Mackay's book on the Longitude, or to professor Vince's Practical Astronomy.

Of correcting the Altitudes of the observed Objects.—When a lunar observation is made, the first object is to clear the altitudes from semidiiameter, dip, refraction, and parallax, according to usual practice. The moon's parallax in altitude must next be calculated: by saying, "As radius is to the sine of her zenith distance, so is the sine of her horizontal parallax (as given in the Nautical Almanac) to the sine of her parallax in altitude."

In correcting the moon's altitude, an allowance should be made for the augmentation of her semidiiameter, which gradually takes place from the horizon to the zenith. This increase is given, in the 4th of the Requisite Tables, for every 5 degrees of altitude, which correction is to be added to her horizontal semidiiameter given in the Nautical Almanac.

The augmentation of the moon's semidiiameter is caused by her being nearer to the spectator in the zenith than in the horizon, by a semidiiameter of the earth—for the apparent magnitude of a body is in the inverse ratio of its distance from the observer; and as the earth's semidiiameter bears a very sensible proportion to the moon's distance, she is seen under the greatest angle in the zenith, which angle gradually diminishes to the horizon.

There are other corrections of the altitudes, which may be necessary in cases of peculiar nicety, but which are seldom noticed at sea. These are, an allowance for the contraction of the vertical semidiameters of the sun and moon by refraction; a correction of the moon's parallax, supposing the earth an oblate spheroid; a correction for the refraction according to the actual state of the atmosphere, as shown by a thermometer and barometer, and not according to the mean astronomical refraction which is commonly used. These corrections, though perhaps necessary towards the perfection of this problem, being very small, and frequently counteracting each other, are generally considered of little consequence in nautical practice, where greater errors are unavoidable.

From the corrected Altitudes to find the true Distance.—It is easy to conceive that by a lunar observation, the three sides of a spheric triangle are measured in the heavens, which sides are the apparent co-altitudes of the observed bodies, and their apparent distance asunder.

The co-altitudes or zenith distances being corrected, the question is, to find the true distance between the observed bodies; but here only two things are given, and therefore it cannot be performed until the angle at the zenith is known, which is determined from the three given sides of the triangle, by the rules of spheric trigonometry. See KELLY's *Spherics*, pa. 182.

As the effects of parallax, refraction, &c, operate only in a vertical direction, it is evident that the corrections of the zenith distances, or containing sides, will not change the included angle at the zenith; and therefore three things are now known, namely, the corrected zenith distances and the included angle, whence the other side is determined by spherics, and this side is the true distance sought.

A general View of the different Methods of working the lunar Observations.—Few problems have ever been more investigated and studied, than that of clearing the lunar distances, and many ingenious methods have been devised for contracting the operation. These methods are founded on some of the following general principles. The first is spheric trigonometry, as before explained; the second is

the doctrine of proportional errors, by which the effects that the errors in the altitudes produce on the distance, are solved by fluxions, or by the differential calculus; and a third principle has been lately discovered, which is founded on the properties of a quadrangle inscribed in a circle, as explained and exemplified by the inventor, Dr. Andrew, in his Astronomical and Nautical Tables.

Various methods of working the lunar observations have been devised, chiefly by Halley, Euler, Mayer, Maelkyn, Dunthorn, Lyons, Witchell, Burrow, Borda, Wales, Mackay, Kelly, Gerrard, Andrew, and Mendoza. The methods of the two last authors appear to be the most concise, but all are sufficiently correct, and seamen generally prefer such as they have first learnt. It may indeed be observed, that operations which appear the most concise, are not always the most expeditiously performed; as much depends on the number and variety of tables required, and the manner of applying them. No method has hitherto obtained an exclusive preference over the rest, nor does it appear possible to reduce the calculation to a conciseness to answer the general wants or wishes of seamen; and hence, other modes have been devised of obtaining approximate solutions by projection or graphic operation.

Graphic Operations.—The first graphic method for clearing the distances, was that published by Lacaille, called the Chassis de Reduction, which has since been copied by Lalande, Mackay, and others. It is an orthographic projection, consisting of a great number of lines accurately drawn, and various scales for obtaining the different corrections.

On similar principles, and for the same purpose, the late Mr. James Fergusson, teacher of navigation and examiner in that science to the East-India Company, constructed a *Rotula*, or longitude instrument, which did great credit to him as a man of science.

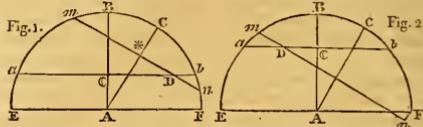

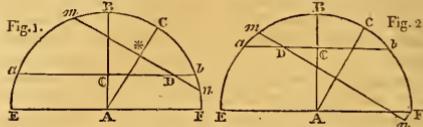

Another graphic operation, of a different description, was executed by Mr. George Margetts, and published in 1790. It consists of 70 large plates, containing numerous lines drawn from the solution of lunar distances in Dr. Shepherd's Tables. By Margett's Longitude Tables, the solution of a lunar observation may be obtained in about one-fourth of the time required by calculation; and the answer, though not given as perfectly accurate, is sufficiently so for the general purposes of navigation.

Dr. Kelly has devised an orthographic projection founded on the fluxional analogies of spheric triangles, which is published in his Introduction to Spheres and Nautical Astronomy, where an investigation of its principles is given (pa. 195, edit. 2, 3, and 4), with a demonstration, showing that, in proper altitudes, it cannot essentially err, but must give the true distance within a few seconds. The simplicity of this projection is extremely curious, as giving an approximate solution of a complicated problem, by drawing four right lines only, from the scale of chords, and it must therefore be very useful, especially where expedition is required.

Since the first appearance of this projection, which was in 1795, several mathematicians have turned their attention to the subject, and various ingenious plans have been proposed for shortening and simplifying the operation, among which may be mentioned a *Rotula* by Mr. B. Donie of Bristol, which solves the problem with great accuracy.

The following is an abstract of Kelly's Projection, inserted here by permission of the author.

Exam. 1. Given the apparent distance between the moon, and the sun, or a star - - - 30°
The moon's altitude - - - 20
The star's altitude - - - 40
The moon's horizontal parallax - - - 1
To find the true distance.

With the sweep of 60°, from a scale of chords, describe a semicircle, and bisect it by the perpendicular AB . On the right hand side of this line, from B to c , lay off 30°, the apparent distance, from the same scale. Also the moon's altitude, 20°, from E to a , and from F to b ; and draw ab . Then lay off the sun's co-altitude, 50°, both ways from c to m and n , and draw mn , intersecting ab in d .—Then is $d \propto$ the mean correction, to be measured on the scale of chords, calling every degree on the scale a minute; which must be reduced to the true correction by the following general rule: first observing that if this line $d \propto$ falls on the right-hand side, as in fig. 1, the correction is negative or subtractive; but if on the left, as in fig. 2, the correction is positive or additive.

RULE. Multiply the mean correction, $d \propto$, by the given horizontal parallax, and divide the product by 62 when the correction is subtractive, but by 53 when it is additive. Then the quotient will be the true correction. Thus, in the first case $d \propto$ measures $41\frac{1}{4}$, or $41^{\circ} 15'$, and being subtractive, it is multiplied by 60, and divided by 62, which gives the true correction $39^{\circ} 55'$, being only one second more than by calculation; hence the true distance is $29^{\circ} 20' 5''$.

Exam. 2. Given the apparent distance 30°
The moon's altitude 40
The sun or star's altitude 20
The moon's horizontal parallax 1
To find the true distance.

Describe the semicircle as before (or a greater arc to n if wanted, as in fig. 2), and lay off the apparent distance $BC = 30^{\circ}$. Make ea and $fb = 40^{\circ}$ the moon's altitude, and draw ab . Lay off the star's co-altitude 70° , from c to m and n , and drawn mn . Then is $d \propto$ the mean correction, which here measures $24^{\circ} 10''$; and being multiplied by 60, and divided by 53, it gives $27^{\circ} 21''$ for the true correction, being only $3''$ more than the result by calculation; and the correction being additive, it gives $30^{\circ} 27' 21''$ for the true distance.

This projection will appear still more simple by drawing the triangle only, and laying off the altitudes from the line of sines. Thus, in fig. 1, project the angle $BAC = 30^{\circ}$, and make $A \propto = \sin e = \sin 20^{\circ}$, also $A *$ = 40° . Then perpendicular lines from C and $*$ will meet in d as before.

From the foregoing projection, the following general rules are obvious, for estimating the correction of a lunar observation without any operation.—1. When the moon is lower than the star, the correction is always subtractive; but when it is the higher body, beyond a certain extent,

and within a certain limit as to distance, the correction is additive.—2. When the sine of the moon's altitude is to that of the star's, as radius is to the cosine of the distance, then the true and apparent distances are nearly equal: but when the moon's altitude is greater than the star's, beyond that proportion, the correction is additive; except when the distance is about 90° , or more, and then it is subtractive.—3. Though the correction additive does not occur so frequently as the subtractive, nor is it in general so great, yet it admits of a wider variation, being sometimes above 1° ; but the subtractive correction is never quite so much.

The author of this construction further observes that, " In solving the lunar problem by this projection, a slate will perhaps be found more convenient than paper; and a large scale of chords is, of course, preferable to a small one.—That, in the foregoing examples, round numbers have been chosen for the sake of simplicity; but fractional quantities might have been adopted with equal accuracy. It is not however presumed that the results of all lunar problems will be alike correct by this method, but they will be found seldom to vary above half a minute from the true distance; which cannot be deemed of much importance, when it is considered that greater inaccuracies are perhaps unavoidable in the observations. It is extremely difficult, for instance, to ascertain within a minute the true point of contact between the moon and the sun or star. Their altitudes too are often doubtful, on account of the changes of refraction, and the haziness of the horizon: to which may be added the imperfection of instruments, the incompetency of observers, and even the inaccuracy of the lunar tables themselves, which have been hitherto only in a progressive state of improvement.

It is well known that, from various unavoidable causes, all astronomical computations are but approximations to perfect accuracy; and that in this science difficulties and obstructions are much greater at sea than at land. It is also allowed, that of all the operations in nautical astronomy, the lunar problem is the most embarrassing, and the most liable to error; and it is likewise agreed that the best mode of diminishing such uncertainties, is by multiplying the observations, and taking a mean of many trials. Hence an approximate method, like the present, which cannot essentially err, and which is performed with so much expedition, must be highly useful, as affording the most time for repeating the observations. Even where no such repetitions are required, this projection may be advantageously used as a substitute for troublesome computations, particularly in the common course of nautical practice. It may indeed be observed, that the more urgent duties of seamen seldom allow them sufficient leisure for tedious numerical operations. Besides, it seems rather a vain pursuit to sacrifice so much time in search of a few seconds, where there are probably errors of whole minutes in the data. It may even be observed, that long and laborious calculations contain within themselves many sources of error, to which projection is not exposed."

LUNAR Month, is either periodical, synodical, or illuminative: which see; also **MONTH**.

LUNAR Year, consists of 354 days, or 12 synodical months, of $29\frac{1}{2}$ days each. See **YEAR**. In the early ages, the lunar year was used by all nations; the variety of course being more frequent and conspicuous in this planet, and consequently better known to men, than those of any other. The Romans regulated their year, in part,

by the moon, even till the time of Julius Caesar. The Jews too had their lunar month and year.

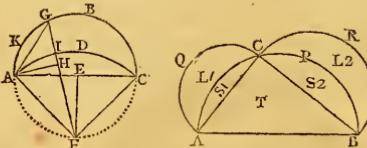

LUNAR Dial, Eclipse, Horoscope, and Rainbow. See the several substantives.

LUNATION, the period or time between one new moon and another; it is also called the synodical month, consisting of 29 days 12 hrs. 44 m. 3 sec. 11 thirds; exceeding the periodical month by 2 d. 5 hrs. 0 m. 55 sec.

LUNE, or **LUNULA**, or little moon, is a geometrical figure, in form of a crescent, terminated by the arcs of two circles that intersect each other within.

Though the quadrature of the whole circle has never been effected, yet many of its parts have been squared. The first of these partial quadratures was that of the lunula, given by Hippocrates of Scion, or Chios; who, from being a shipwrecked merchant, commenced geometer. But though the quadrature of the lune be generally ascribed to Hippocrates, yet Proclus expressly says it was found out by Oenopidas of the same place. See Heinius in Men. de l'Acad. de Berlin, tom. ii. p. 410, where he gives a dissertation concerning this Oenopidas. See also **CIRCLE**, and **QUADRATURE**.

The lune of Hippocrates is this: Let ABC be a semicircle, having its centre E , and ADC a quadrant, having its centre F ; then the figure $ABCD$, contained between the arcs of the semicircle and quadrant, is his lune; and it is equal to the right-angled triangle ACF , as is thus easily proved. Since $AF^2 = 2AE^2$, that is, the square of the radius of the quadrant equal to double the square of the radius of the semicircle; therefore the quadrantal area $ADCF$ is = the semicircle $ABCE$; from each of these take away the common space $ADCEA$, and there remains the triangle $ACF =$ the lune $ABCD$.

Another property of this lune is, that if FG be any line drawn from the point F , and AH perpendicular to it; then is the intercepted part of the lune $AGIA$ = the triangle AGH , cut off by the chord line AG ; or in general, that the small segment $AKGA$ is equal to the trilineal $AITHA$. For, the angle AFG being at the centre of the one circle, and at the circumference of the other, the arcs cut off AG , AT are similar to the wholes ABC , ADC ; therefore the small seg. $AKGA$ is to the semicegment $AITHA$, as the whole semicircle $ABCA$, to the semicegment or quadrant $ADCF$, that is in a ratio of equality.

Again, if ABC (fig. 2) be a triangle, right-angled at C , and if semicircles be described on the three sides as diameters; then the triangle T (ABC) is equal to the sum of the two lunes $L1$, $L2$. For, the greatest semicircle is equal to the sum of both the other two; from the greatest semicircle take away the segments $S1$ and $S2$, and there remains the triangle T ; also from the two less semicircles take away the same two segments $S1$ and $S2$, and there remains the two lunes $L1$ and $L2$; therefore the triangle $T = L1 + L2$, the two lunes.

LUNETTE, in Fortification, an enveloped counterguard, or mound of earth, made beyond the second ditch, oppo-

site to the place of arms; differing from the ravelins only in their situation. Lunettes are usually made in wet ditches, and serve the same purpose as fausse-brays, to defend the passage of the ditch.

LUPUS, *the Wolf*, a southern constellation, joined to the Centaur, containing together 19 stars in Ptolemy's catalogue, but 24 in the Britannic catalogue.

LYNX, a constellation of the northern hemisphere, composed by Hevelius out of the unformed stars. In his catalogue it consists of 19 stars, but in the Britannic of 44.

LYONS (ISRAEL), a respectable mathematician and botanist, was the son of a Polish Jew silversmith, and teacher of Hebrew at Cambridge in England, where he had come to settle, and where young Lyons was born, 1739. He was a very extraordinary young man for parts and ingenuity; and showed very early in life a great inclination to learning, particularly mathematics, on which account he was much patronized by Dr. Smith, master of Trinity-college. About 1755 he began to study botany, which he continued occasionally till his death; in which he made a considerable progress, and could remember not only the Linnaean names of almost all the English plants, but even the synonyma of the old botanists; and he had prepared large materials for a *Flora Cantabrigiensis*, describing fully every part of each plant from the specimen, without being obliged to consult, or being liable to be misled by, former authors.

In 1758, he obtained much celebrity by publishing A Treatise on Fluxions, dedicated to his patron, Dr. Smith; and in 1763, *Fasciculus Plantarum circa Cantabrigiam*, &c. In the same year, or the year before, he read lectures on botany at Oxford with great applause, to at least 60 pupils; but he could not be prevailed on to make a long absence from Cambridge.

Mr. Lyons was some time employed as one of the computers of the Nautical Almanac; besides which, he received frequent presents from the Board of Longitude for his own inventions.—He had studied the English history;

and could quote whole passages from the monkish writers of antiquity. He could read Latin and French with ease, but wrote the former indifferently. He was appointed by the Board of Longitude to sail with Capt. Phipps, in his voyage towards the north pole, in 1773, as astronomical observator; which office he discharged much to the satisfaction of his employers. After his return from this voyage, he married, and settled in London, where he died of the measles about two years after.

At the time of his death he was engaged in preparing for the press, a complete edition of all the works of the learned Dr. Halley; a work very much wanted.—His Calculations in Spherical Trigonometry abridged, were printed in the Philos. Trans. vol. 65, for the year 1775, pa. 470.—After his death, his name appeared in the title-page of A Geographical Dictionary, the astronomical parts of which were said to be "taken from the papers of the late Mr. Israel Lyons of Cambridge, author of several valuable mathematical productions, and astronomer in Lord Mulgrave's voyage to the northern hemisphere."—The astronomical and other mathematical calculations, printed in the account of Captain Phipps's voyage towards the north pole, mentioned above, were made by Mr. Lyons. This appeared afterwards, by the acknowledgment of Captain Phipps, when Dr. Horsley detected a material error in some part of them, in his Remarks on the Observations made in the late Voyage, &c., 1774.

The Scholar's Instructor, or Hebrew Grammar, by Israel Lyons, teacher of the Hebrew tongue in the University of Cambridge, the 2d edit. &c., 1757, 8vo, was the production of his father; as was also another treatise printed at the Cambridge press, under the title of Observations and Enquiries relating to various parts of Scripture History, 1761.

LYRA, *the Harp*, a constellation in the northern hemisphere, containing 10 stars in Ptolemy's catalogue, 11 in Tycho's, 17 in Hevelius's, and 21 in the Britannic catalogue.

ADDENDUM.

After line 17, col. 2, page 341, on the nature of comets, add:—Dr. Herschel, in several volumes of the Philos. Trans. states his opinions of the nature and constitution of comets. His hypothesis is, that they are formed of the condensed nebulous matter diffused through the universal space, and lying within the sphere of the sun's activity; which thus gives them a revolutionary motion in an elliptic orbit. Of the same opinion also is Count Laplace, as appears by a learned memoir on the subject, in the *Connoissance des Temps* for the year 1816.

ERRATA.

- Pa. 135, col. 2, end of line 6 from the bottom, for N^2 , read $2N$.
- 269, — 1, lin. 24, 25, for Chichester, read Chester.
- 480, — 2, end of line 28, for it , read 1 .
- 484, — 1, line 20, for plate viii, read plate x.
- 484, — 2, line 5, for k , read K .
- 698, — 1, line 28, for $\frac{1}{2}$, read $\frac{1}{2}T$.
